Synchronization for discrete mean-field rotators

Benedikt Jahnel* Christof Külske†

Abstract
We analyze a non-reversible mean-field jump dynamics for discrete q-valued rotators and show in particular that it exhibits synchronization. The dynamics is the mean-field analogue of the lattice dynamics investigated by the same authors in [30] which provides an example of a non-ergodic interacting particle system on the basis of a mechanism suggested by Maes and Shlosman [37].

Based on the correspondence to an underlying model of continuous rotators via a discretization transformation we show the existence of a locally attractive periodic orbit of rotating measures. We also discuss global attractivity, using a free energy as a Lyapunov function and the linearization of the ODE which describes typical behavior of the empirical distribution vector.

Keywords: Interacting particle systems; non-equilibrium; synchronization; mean-field systems; discretization; XY model; clock model; rotation dynamics; attractive limit cycle.

1 Introduction
Systems of interacting classical rotators (S^1-valued spins) on the sites of a lattice and also on different graphs have been a source of challenging and fruitful research in mathematical physics and probability. One likes to understand the nature of their translation-invariant phases ([24, 3]), and the dependence on dimensionality ([20]); one likes to understand the influence of different types of disorder, may it be destroying long-range order ([1]) or even creating long-range order ([10]); their dynamical properties, the difference that discretizations of the spin values make to the system (see the clock models in [22]). There is some similarity between rotators and massless models of real-valued unbounded fields (gradient fields), see [21, 16, 9]. Roughly speaking the existence of ordered states for rotator models corresponds to existence of infinite-volume gradient states.

There is usually much difference between the behavior of massless models of continuous spins and models of discrete spins. The low energy excitations of the first are
Synchronization for discrete mean-field rotators

waves (see however the discrete symmetry breaking phenomenon of [10]), the excitations at very low temperatures of the latter can be described and controlled by contours (see [6]).

There are however surprising situations when discrete models and continuous models behave the same: It is known that there can be even a continuum of extremal Gibbs measures for certain discrete-spin models (see [24] for results in the nearest neighbor $q$-state clock model in an intermediate temperature regime). A route to create such a discrete system which is closely related but different from the clock models with nearest neighbor interaction goes as follows: Apply a sufficiently fine discretization transformation to the extremal Gibbs measures of an initial continuous-spin model in the regime where the initial system shows a continuous symmetry breaking. Then show that the resulting uncountably many discretized measures are proper extremal Gibbs measures for a discrete interaction (see [17, 30]). The model we are going to study here will also be of this type.

There is another line of research leading to rotator models: Dynamical properties of rotator models from the rigorous and non-rigorous side have attracted a lot of interest from the statistical mechanics community and from the synchronization community (see [37, 4, 28]). Usually one studies a diffusive time-evolution of $S^1$-valued spins of mean-field type which tends to synchronize the spins, where the mean-field nature is suggested by applications which come from systems of interacting neurons and collective motions of animal swarms. Typically the dynamics is not reversible here. The first task one faces is to show (non-)existence of states describing collective synchronized motion, depending on parameter regimes. Next come questions about the approach of an initial state to these rotating states under time-evolution (see [4, 5]), influence of the finite system size, and behavior at criticality (see [8]).

Our present research is motivated by a paper of Maes and Shlosman, [37], about non-ergodicity in interacting particle systems (IPS). They conjectured that there could be non-ergodic behavior of a $q$-state IPS on the lattice in space dimensions $d \geq 3$ along the following mechanism involving rotating states. The system they considered was the $q$-state clock model with nearest neighbor scalar product interaction in an intermediate temperature regime where it is proved to have a continuity of extremal Gibbs states which can be labelled by an angle. Then they proposed a dynamics which should have the property to rotate the discrete spins according to local jump rules such that it possesses a periodic orbit consisting of these Gibbs states. On the basis of this heuristic idea of such a mechanism of rotating states, in a previous related work, [30], we considered a very special choice of quasilocal rates for a Markov jump process on the integer lattice in three or more spatial dimensions which provably shows this phenomenon. We were able to show that this IPS has a unique translation-invariant measure which is invariant under the dynamics but also possesses a non-trivial closed orbit of measures. Initialized at time zero according to a measure on this orbit the discrete spins perform synchronous rotations under the stochastic time evolution and don't settle in the time-invariant state. In particular we thereby constructed a lattice-translation invariant IPS which is non-ergodic in time. While such behavior was known to be possible for probabilistic cellular automata (infinite volume particle systems with simultaneous updating in discrete time), see [7], it was not known to occur for IPS (infinite volume particle systems in continuous time) and our example answers an old open question in IPS (Liggett question four of chapter one in [36]).

There are open questions nonetheless in the lattice model. Of course it would be very interesting to see whether the periodic orbit of measures is attractive, what is the basin of attraction, what more can be said about the behavior of trajectories of time-evolved measures, but this is open. We also don't know whether the original Maes-Shlosman
conjecture is true and a simpler rotation dynamics with nearest neighbor interactions also behaves qualitatively the same in an intermediate temperature regime.

In this paper let us therefore put ourselves to a mean-field situation and investigate whether we find analogies to the lattice and what more can be said now. This is interesting in itself since rotator models are naturally so often studied in a mean-field setting. What is a good version of a jump dynamics for discrete mean-field rotators implementing the Maes-Shlosman mechanism? Is there synchronisation for such a model as it is known to happen in the Kuramoto model ([26, 11])? If yes, what can we say about attractivity of the orbit of rotating states? Are there other attractors?

Note that a very first naive attempt to define a discrete-spin mean-field dynamics showing synchronisation does not work: the simple scalarproduct interaction \(q\)-state clock model does not have continuous symmetry breaking at any \(\beta\). The model and its dynamics will rather appear as a discretization image of the continuous model on the level of measures. We consider the mean-field rotator model under equal-arc discretization into \(q\) segments and define associated jump rates. Next we give criteria on the fineness of the discretization for existence and non-existence of the infinite-volume limit, and discuss a path large deviation principle (LDP) for empirical measures and the ODE for typical paths. We prove that the discretization images of rotator Gibbs measures in the phase-transition region form a locally attractive limit cycle. Further we investigate local attractivity of the equidistribution and determine the non-attractive manifold. The question of global attractivity can be answered in the following way: Apart from measures with higher free energy than the equidistribution that get also trapped in the locally attractive manifold of the equidistribution, all measures are attracted by the limit cycle.

Summarizing, our mean-field results show many analogies to mean-field models of continuous rotators, they are in nice parallel to the behavior of the corresponding lattice system, but they go further since no stability result is known in the latter. It would be a challenge to see to what extent this parallel really holds.

In the remainder of this introduction we present the construction and the main results without proofs.

### 1.1 Model and rotation dynamics

We look at continuous-spin mean-field Gibbs measures in the finite volume \(V_N = \{1, \ldots, N\}\) which are the probability measures on the product space \((S^1)^N\) equipped with the product Borel sigma-algebra, defined by

\[
\mu_{\Phi,N}(d\sigma_{V_N}) = \frac{\exp(-H_N(\sigma_{V_N}))\alpha^\otimes N(d\sigma_{V_N})}{\int_{(S^1)^N} \exp(-H_N(\sigma_{V_N}))\alpha^\otimes N(d\sigma_{V_N})}
\]

where \(\alpha\) is the Lebesgue measure on \(S^1\). Here the energy function

\[
H_N(\sigma_{V_N}) = N\Phi\left(L_N(\sigma_{V_N})\right)
\]

depends on the spin configuration \(\sigma_{V_N} = (\sigma_i)_{i\in V_N}\) only through the empirical distribution \(L_N(\sigma_{V_N}) = \frac{1}{N} \sum_{i=1}^{N} \delta_{\sigma_i}\). For details on this mean-field setup see [13]. Let us consider real-valued potentials \(\Phi\) defined on the space of probability measures \(\mathcal{P}(S^1)\) on the sphere \(S^1\) of two-body interaction type,

\[
\Phi(\nu) = \int \nu(ds_1) \int \nu(ds_2) V(s_1, s_2)
\]

where \(V\) is a symmetric pair-interaction function on \((S^1)^2\). We will refer to this model as the *planar rotator model*. For the most part of the paper we will further specialize to
the standard scalar product interaction with coupling strength $\beta > 0$

$$V(s_1, s_2) = -\frac{\beta}{2} \langle e_s, e_s \rangle$$

where $e_s = (\cos s, \sin s)^T$ is the unit vector pointing into the direction with angle $s$. Recall as a standard fact that the distribution of the empirical measures $L_N$ under $\mu_{\beta,N}$ obeys a LDP with rate $N$ and rate function given by the free energy

$$\Psi(\nu) = \Phi(\nu) + S(\nu|\alpha) - \inf_{\tilde{\nu}} \left( \Phi(\tilde{\nu}) + S(\tilde{\nu}|\alpha) \right)$$

(1.2)

where $\nu$ denotes the relative entropy (for details on LDP theory see [12, 28]). In the usual short notation let us write

$$\mu_{\beta,N}(L_N \approx \nu) \approx \exp(-N\Psi(\nu)).$$

It is well known (see [42]) that there exist multiple minimizers of $\Psi$ in the scalar product model if and only if $\beta > \beta_c = 2$ corresponding to a second-order phase transition in the inverse temperature at the critical value 2 and a breaking of the $S^1$-symmetry.

1.1.1 Deterministic rotation, discretization and finite-volume Markovian dynamics for discretized systems

For any real time $t$ we look at the joint rotation action $R_t : (S^1)^N \mapsto (S^1)^N$ given by the sitewise rotation of all spins, that is $(R_t \omega_N)_i = R_t \omega_i$ where $R_t e_s = e_{(s+t) \text{mod}(2\pi)}$.

Let $\mu_N$ be a probability measure on $(S^1)^N$ which has a smooth Lebesgue density relative to the product Lebesgue measure on $(S^1)^N$. Denote the measure resulting from this deterministic rotation action $R_t$ by $\mu_{\beta,N} := R_t \mu_N$.

Next denote by $T$ the local discretization map (local coarse-graining) with equal arcs of the sphere written as $[0, 2\pi)$ to the finite set $\{1, \ldots, q\}$, that is with $\nu := [\frac{2\pi}{q} (k-1), \frac{2\pi}{q} k]$, $S^1 = \bigcup_{k=1}^q S_k$ and $T(s) = k$ if $s \in S_k$. Extend this map to configurations in the product space by performing it sitewise. In particular we will consider images of measures under this discretization map $T$.

We will see that discretization after rotation of a continuous measure can be realized as a jump process. In order to define such a Markov jump process on the discrete-spin space $\{1, \ldots, q\}^N$ we need some preparations. The following proposition describes the interplay between the discretization map $T$ and the deterministic rotation and is the starting point for the introduction of the dynamics we are going to consider.

**Proposition 1.1.** There is a time-dependent linear generator $Q_{\mu_{\beta,N}}$, acting on discrete observables on the discrete $N$-particle state space, $g : \{1, \ldots, q\}^N \mapsto \mathbb{R}$, such that an infinitesimal change of $T(\mu_{\beta,N},t)(g) = \int \mu_N(\omega) g(R_t \omega)$ can be written as

$$\lim_{\varepsilon \downarrow 0} \frac{1}{\varepsilon} \left( T(\mu_{\beta,N,t+\varepsilon})(g) - T(\mu_{\beta,N,t})(g) \right) = T(\mu_{\beta,N,t})(Q_{\mu_{\beta,N}}g). \quad (1.3)$$

This generator takes the form of a sum over single-site terms

$$Q_{\mu_{\beta,N}} g(\sigma'_{V_N}) := \sum_{i=1}^N c_{\mu_{\beta,N}}(\sigma'_{V_N}, \sigma'_{V_N} + 1_i) \left( g(\sigma'_{V_N} + 1_i) - g(\sigma'_{V_N}) \right) \quad (1.4)$$

where $\sigma'_{V_N} + 1_i = \sigma'_{j} + 1_{j \sim i}$ (modulo $q$). Here $c_{\mu_{\beta,N}}$ are certain time-dependent rates for increasing a coordinate by 1 at single sites which have the feature to depend on time (only) through the measure $\mu_{\beta,N,t}$.
Synchronization for discrete mean-field rotators

Note, here and in what follows we obey the convention to write primes whenever we speak of elements of coarse-grained spaces. The generator $Q_{\mu}^{N,t}$ defines a Markov jump process (a continuous-time Markov chain) on the finite space $\{1, \ldots, q\}^N$. There are only trajectories possible along which the variables $\sigma'_i$ increase their values by one unit along the circle of $q$ units according to the appropriate rates. An explicit expression for the rates in terms of the underlying measure can be found in formula (2.1). The process we are going to study will be of this type.

Let us specify to the case of a mean-field Gibbs measure $\mu_{\Phi,N}$ with a rotation-invariant interaction $\Phi$. Then $\mu_{\Phi,N}=\mu_{\Phi}$ stays constant under time-evolution and consequently the rates become time-independent. From permutation invariance we see that the resulting jump process obtained by mapping the trajectories of the paths $\sigma_{VN}(t)$ to trajectories of the empirical distributions $L_N(\sigma_{VN}(t))$ is a Markov process with generator which can be written in the form

$$Q^\text{emp}_N f(\nu') = N \sum_{k=1}^{q} \nu'(k) c^\text{emp}_N(k,\nu') \left( f(\nu' + \frac{1}{N} (\delta_{k+1} - \delta_k)) - f(\nu') \right).$$ (1.5)

Here $f : P(\{1, \ldots, q\}) \mapsto \mathbb{R}$ is an observable on the simplex of $q$-dimensional probability vectors, $\delta_k$ is the Dirac measure at $k \in \{1, \ldots, q\}$ and $c^\text{emp}_N(k,\nu')$ are the resulting rates (given in (2.3)) describing the change of the empirical distribution at size $N$ when one particle changes its value from the state $k$ to $k+1$.

As a result of this construction of a Markovian dynamics we have the following corollary.

**Corollary 1.2.** Consider a mean-field Gibbs measure $\mu_{\Phi,N}$ for a rotation invariant potential $\Phi$. Then the stochastic dynamics on the space of empirical distributions $P(\{1, \ldots, q\})$ with the above rates $c^\text{emp}_N(k,\nu')$ preserves the empirical distribution of the discretized mean-field Gibbs measure $(T_{\mu_{\Phi,N}}(L_N \in \cdot)) \in P(\{1, \ldots, q\})$.

So far the construction of a mean-field dynamics for discrete rotators is largely in parallel to our construction of a dynamics for a non-ergodic IPS on $\mathbb{Z}^d$ as presented in [30].

Our present aim for the mean-field setup is to understand large-$N$ properties, mean-field analogues of rotating states (that we will refer to as the periodic or closed orbit) and mean-field analogues of non-ergodicity. We note that at finite $N$ of course we do not see a non-trivial closed orbit of measures. We will have to go to the limit $N \uparrow \infty$ to see reflections in the mean-field system of the non-ergodicity proved to occur for the IPS on the lattice. The picture one expects is the following: The empirical distribution (or profile) of a finite but very large particle system will become close in $O(1)$ time to an empirical distribution (almost) on the periodic orbit. Then it will follow the orbit until a time large enough such that the finiteness of the system size will be felt. From that on it will not be sufficient to talk about a single profile anymore, rather more generally about a distribution of profiles, which, as time goes by, will mix over different angles along the orbit with equal probability. The relevant $N$-dependent mixing time we will not discuss in this paper. The control of closeness of the stochastic evolution up to finite times will be delivered by the path LDP which we are going to describe. Then we will analyze the typical behavior of the minimizing paths. While doing that we will be able to obtain additional information in mean field (which seem hard to get on the lattice) about stability of the periodic orbit under the dynamics.

1.1.2 Infinite-volume limit of rates for fine enough discretizations

To be able to understand the large-$N$ behavior we must look more closely to the rates $c^N(k, \nu)$ and their large-$N$ limit. As it turns out, the existence and well-definedness is not completely automatic, but only holds if the discretization is sufficiently fine. This is an issue which is related to the appearance of non-Gibbsian measures under discretization transformations (see for example [15, 17, 18]) and provides a concrete application of the techniques used in Gibbs non-Gibbs theory. On the constructive side we have the following result in our mean-field setup.

Theorem 1.3. For any smooth mean-field interaction potential $\Phi : \mathcal{P}(S^1) \to \mathbb{R}$ there is an integer $q(\Phi)$ such that for all $q \geq q(\Phi)$ the rates (2.3) have the infinite-volume limit

$$c(k, \nu') = \frac{\exp(-d\Phi_{\nu'}(\delta_{\frac{k}{q}} - \nu'))}{\int_{S^1} \exp(-d\Phi_{\nu'}(\delta_{\sigma} - \nu'))\alpha(d\sigma)}$$

where the measure $\nu'$ is the unique solution of the constrained free energy minimization problem $\nu \mapsto \Phi(\nu) + S(\nu;\alpha)$ in the set of $\nu \in \mathcal{P}(S^1)$ with given discretization image $\nu'$, in other words in the set $\{\nu \in \mathcal{P}(S^1) | T(\nu) = \nu'\}$.

Here $d\Phi_{\nu}(\delta_{\sigma} - \nu)$ is the differential of the map $\Phi$ taken in the point $\nu \in \mathcal{P}(S^1)$ applied to the signed measure $\delta_{\sigma} - \nu$ on $S^1$ with mass zero. It has the role of a mean field that a single spin feels when the empirical spin distribution in the system is $\nu$.

The assumption of fine enough discretizations $q \geq q(\Phi)$ ensures that the minimizer is unique and moreover Lipschitz continuous in total-variation distance as a function of $\nu'$ (see the proof of Lemma 2.2). For $q < q(\Phi)$ existence of the limiting rates can not be ensured and indeed fails in the scalarproduct model for given $q$ and low enough temperature, see below. The constrained minimizer $\nu'$ can be characterized as the unique solution of a typical mean-field consistency equation which reduces to a finite-dimensional equation in the case of the scalarproduct model. This uniqueness of the constrained free energy minimization is closely related to the notion of a mean-field Gibbs measure in terms of continuity of limiting conditional probabilities (see [17, 34]). Loosely speaking, the absence of phase-transition for the constrained model equals Gibbsianness of the transformed model. In mean-field this means, uniqueness of the constrained free energy minimization problem equals existence and continuity of limiting single site conditional probabilities. Absence of this continuity determines non-Gibbsianness and therefore the issue of Gibbsianness versus non-Gibbsianness is closely connected to the issue of the existence of the infinite-volume dynamics.

The continuous spin value appearing in the definition of the rate to jump from $k$ to $k+1$ given by $\frac{k}{q}$ is the boundary between the segments of $S^1$ labelled by $k$ and by $k+1$. It is illuminating to compare the expression for the rates to the ones obtained for the non-ergodic IPS on the lattice from [30] and observe the analogoy.

To get more concrete insight we specialize to the scalarproduct model where fineness criterion on discretization and form of rates are (more) explicit. We have the following proposition.

Theorem 1.4. Consider the standard scalarproduct model, let $\beta > 0$ be arbitrary (possibly in the phase-transition regime $\beta > 2$) and $q$ be an integer large enough such that $\beta \sin^2(\frac{\pi}{q}) < 1$. Then the constrained free energy minimizer $\nu'$ is unique and the jump rates take the form

$$c(k, \nu') = \frac{e^{\beta(e^{\frac{2\pi}{q} \cdot M_k(\nu')})}}{\int_{S^1} e^{\beta(e^{\frac{2\pi}{q} \cdot M_k(\nu')}\alpha(d\omega))}, \text{ for } k = 0, \ldots, q - 1$$ (1.6)
where \( \nu' \mapsto M_{\beta}(\nu') := \int \nu'^{\prime}(d\omega)e^{\omega} \) takes values in the two-dimensional unit disk.

The vector \( M_{\beta}(\nu') \) is the magnetization of the minimizing continuous-spin measure \( \nu' \), which is constrained to \( \nu' \). It is implicitly defined and can be computed from the solution of a mean-field fixed point equation.

The above criterion on the fineness of the discretization is a mean-field version of the sufficient criterion for Gibbsianness of discretized lattice measures from [32], [17], [30]. The correspondence between Gibbsianness and the existence of the infinite-volumes rates above, comes from the fact, that in both cases hidden phase-transitions must be excluded. The given criterion is stronger than an application of the criterion for preservation of Gibbsianness under local transforms from [33] would give (where however more general local transformations were considered).

We note that while some criterion on \( q \) is necessary the present criterion is probably not sharp. Below we present an example where multiple constrained minimizers do actually occur (corresponding to non-Gibbsianness of the discretized model) which shows that large-\( \beta \) asymptotics of the bound on \( q \) is correct. The corresponding criterion is given in Section 2.2 Equation (2.11).

### 1.1.3 Limiting dynamical system from path LDP as \( N \uparrow \infty \)

It is possible to formulate a path LDP for our dynamics. The infinite-volume limit of the rates enters into the rate function. This rate function is a time-integral involving a Lagrangian density (see (2.3)). In the present introduction we restrict ourselves to formulate as a consequence the following (weak) law of large numbers (LLN) on the path level, for simplicity restricted to the planar rotor model.

**Theorem 1.5.** Let \( \beta \sin^{2}\left(\frac{\pi}{q}\right) < 1 \), \( \tau \in (0, \infty) \) be a finite time horizon. Let \( (X_{t})_{0 \leq t \leq \tau}^{N} \) be the Markov jump process with generator \( Q_{N}^{\text{emp}} \) started in an initial probability measure \( \nu_{0}' \) on \( \{1, \ldots, q\} \). Then we have

\[
(X_{t})_{0 \leq t \leq \tau}^{N} \xrightarrow{N \to \infty} (\phi(t, \nu_{0}'))_{0 \leq t \leq \tau}
\]

in the uniform topology on the pathspace, where the flow \( \phi(t, \nu_{0}') \) is given as a solution to the \((q-1)\)-dimensional ordinary differential equation

\[
\frac{d}{dt}\phi(t, \nu_{0}') = F(\phi(t, \nu_{0}')) \tag{1.7}
\]

with initial condition \( \phi(0, \nu_{0}') = \nu_{0}' \), for the vector field \( F(\nu') = (F(\nu')(k))_{k=1,\ldots,q} \) acting on \( \mathcal{P}(\{1, \ldots, q\}) \) with components

\[
F(\nu')(k) = c(k-1, \nu')\nu'(k-1) - c(k, \nu')\nu'(k), \quad k = 1, \ldots, q. \tag{1.8}
\]

While the LLN could also be obtained differently (and maybe more easily) the LDP from which this result follows is of independent interest of course. It provides an interesting link with Lagrangian dynamics. Its proof uses the Feng-Kurtz scheme (see [19]).

The dynamical system with vector field \( F \) introduced above provides the mean-field analogue in the large-\( N \) limit of the non-ergodic IPS from [30]. So one expects that it should reflect the non-ergodic lattice behavior (based on the rotation of states) by showing a closed orbit and we will see that this is really the case.
Synchronization for discrete mean-field rotators

1.2 Properties of the flow

1.2.1 Closed orbit and equivarience property of the discretization map

Now we will come to the discussion of the analogue of the breaking of ergodicity in the IPS in [30] occuring on the level of the infinite-volume limit of the mean-field system. Recall that $\Phi$ is the interaction potential defined in (1.1) and $\Psi$ is the free energy defined in (1.2). Denote the continuous-spin free energy minimizers (infinite-volume Gibbs measures on empirical magnetization) by

$$G(\Phi) := \arg\min_{\nu} (\nu \mapsto \Psi(\nu)).$$

Denote the discrete-spin free energy minimizers by the measures

$$G' := \arg\min_{\nu'} (\nu' \mapsto \Psi'(\nu'))$$

where the discrete-spin free energy function $\Psi'$

$$\Psi'(\nu') := \Psi(\nu|\nu')$$

is defined via the constrained minimization given in Theorem 1.3.

The vector field $F$ has the property that deterministic rotation of free energy minimizers in $P(S^1)$ is reproduced by the flow of free energy minimizers in $P(\{1, \ldots, q\})$. In the phase-transition regime of the planar rotor model the continuous-spin free energy minimizers in $P(S^1)$ can be labelled by the angle of the magnetization values. Hence the vector field $F$ has a closed orbit. We can summarize the interplay between discretization, deterministic rotation of continuous measures and evolution according to the flow $(\phi_t)_{t \geq 0}$ of the ODE for discrete measures in the following picture.

**Theorem 1.6.** The following diagram is commutating

\[
\begin{array}{ccc}
P(S^1) & \xrightarrow{\nu \mapsto R_{\phi} \nu} & G(\Phi) \\
\downarrow T & & \downarrow T \\
P(\{1, \ldots, q\}) & \xrightarrow{\nu' \mapsto \psi(t, \nu')} & G'
\end{array}
\]

This picture is in perfect analogy to the behavior of the IPS from [30]. (Let us point out that the generator from [30] is more involved since it contains another part corresponding to a Glauber dynamics. This part was added for reasons which are not present in the mean-field setup. It will not be treated here.)

1.2.2 Attractivity of the closed orbit

For the following we restrict to the standard scalarproduct model and we assume that we are in the regime $\beta > 2$ where a non-trivial closed orbit exists. We want to understand the dynamics in the infinite-volume limit. In our present mean-field setup this boils down to a discussion of the finite-dimensional ODE, so we are left at this stage with a purely analytical question. Note that our ODE for discrete rotators parallels a non-linear PDE for the continuous rotators with all its intricacies (see [5]). Having the benefit of finite dimensions however we have to deal with the additional difficulty that in our case the r.h.s is only implicitly defined.

As our dynamics is non-reversible it is not clear a priori what the behavior of the free energy $\Psi'$ for the discrete system will be under time evolution. However, since we already know that the ODE has as a periodic orbit, namely the set of discretization...
images of continuous free energy minimizers, we might hope that the free energy $\Psi'$ will work as a Lyapunov function. As it turns out this is the case. A Lyapunov function is a function that decreases along every trajectory of the ODE and hence if one knows the minimizers of the Lyapunov function limiting behavior of the trajectories can be inferred.

**Proposition 1.7.** Under the flow $\varphi(t, \nu')$ the discrete-spin free energy $\Psi'$ is non-increasing, $\frac{d}{dt} \bigg|_{t=0} \Psi'(\varphi(t, \nu')) \leq 0$, for all $\nu' \in \mathcal{P}(\{1, \ldots, q\})$. The free energy does not change, $\frac{d}{dt} \bigg|_{t=0} \Psi'(\varphi(t, \nu')) = 0$, if and only if $\nu' \in \mathcal{G}'$ or $\nu' = \frac{1}{q} \sum_{k=1}^{q} \delta_k$.

The proof is not as obvious as one would hope for and uses change of variables to new variables after which certain convexity properties can be used. This seems to be particular to the standard scalarproduct model. As a corollary we have the attractivity of the periodic orbit formulated as follows.

**Theorem 1.8.** For any starting measure $\nu' \in \mathcal{P}(\{1, \ldots, q\})$ with free energy $\Psi'(\nu') < \Psi'(\frac{1}{q} \sum_{k=1}^{q} \delta_k)$ the trajectory $\varphi(t, \nu')$ enters any open neighborhood around the periodic orbit $\mathcal{G}'$ after finite time $t$.

In other words, starting measures with free energy already lower than the equidistribution will approach the periodic orbit.

### 1.2.3 Stability analysis at the equidistribution

For the case of initial conditions $\nu'$ with free energy $\Psi'(\nu') \geq \Psi'(\frac{1}{q} \sum_{k=1}^{q} \delta_k)$ we only know from the previous reasoning that the trajectories enter any open neighborhood around periodic orbit and equidistribution after finite time. So we are interested in the stability of the dynamics locally around the equidistribution. Computing the linearization of the r.h.s of the ODE from its defining fixed point equation and using discrete Fourier transform we derive explicit expressions for its eigenvalues (see Lemma 3.3 and Figure 3). We see that the linearized dynamics rotates and exponentially suppresses the discrete Fourier-modes of the empirical measure except the lowest one which is expanded. In particular we have the following result which is in analogy to the behavior of the continuous model of [27].

**Theorem 1.9.** Assume that the limiting rates exist, then the equidistribution is locally not purely attractive. The 2-dimensional non-attractive manifold is given by

$$\left\{ \nu' \in \mathcal{P}(\{1, \ldots, q\}) \bigg| \sum_{k=1}^{q} \nu'(k) e^{i \frac{2\pi}{q} lk} = 0 \text{ for all } l \in \{2, \ldots, q-2\} \right\}.$$
Synchronization for discrete mean-field rotators

Figure 1: The black area shows \((\beta, q)\)-regimes where uniqueness of constrained free energy minimizers is guaranteed by the criterion given in Theorem 1.4, in other words our construction certainly works. The light gray and white areas show \((\beta, q)\)-regimes where the complementary criterion \((2.11)\) holds, in other words our limiting dynamics can not be defined. In the intermediate dark gray area we do not know whether our dynamics is well defined. However only in the white area the equidistribution is purely attractive, in the relevant \((\beta, q)\)-regimes we have non-attractivity. All analysis is done for \(\beta > 2\) since we only work in the phase-transition region.

In [17, 25, 33]. The proof of Theorem 1.4 uses the special structure of the standard scalar product interaction to derive a tangible criterion for the fineness of discretization implying uniqueness of constrained minimizers which are needed for the existence of limiting rates for the dynamics. In \((2.11)\) we present a complementary criterion on the coarseness of the discretization ensuring non-uniqueness of constrained minimizers. In Subsection 2.3 we prove global existence of solutions of the infinite-volume dynamics via Lipschitz continuity of the r.h.s. Further we prove Theorem 1.5 employing a LDP on the level of paths.

Section 3 Subsection 3.1 contains the proof of the equivariance property indicated in the diagram of Theorem 1.6. In Subsection 3.2 we derive the time-derivative of the free energy and prove Proposition 1.7. As a consequence we obtain stability of the periodic orbit formulated in Theorem 1.8. Subsection 3.3 is devoted to the local stability analysis at the equidistribution and the proof of Theorem 1.9.

2 Rotation dynamics

2.1 Finite-volume rotation dynamics

We consider the time-dependent generator \((1.4)\) acting on discrete observables on the discrete \(N\)-particle state space and \(\mu_{N,t}(d\sigma_{V_N}) = \rho_{N,t}(\sigma_{V_N}) \alpha ^ \otimes N (d\sigma_{V_N})\) where \(\alpha\) denotes the Lebesgue measure on \(S^1\) and the density \(\rho_{N,t}\) is supposed to be continuous. The time-dependent rates are given by

\[
e_{\mu_{N,t}}(\sigma_{V_N}^t, \sigma_{V_N}^t + 1_i) := \frac{\int_{T^{-1}(\sigma_{V_N}^t)} \rho_{N,t}(\frac{2\pi}{q} \sigma_{V_N}^t, \sigma_{V_N}^t) \alpha ^ \otimes N (d\sigma_{V_N}^t)}{\int_{T^{-1}(\sigma_{V_N}^t)} \rho_{N,t}(\sigma_{V_N}^t) \alpha ^ \otimes N (d\sigma_{V_N}^t)}. \tag{2.1}
\]
Proof of Proposition 1.1: It suffices to check (1.3) for $g = 1_{\nu_N}$. We have

$$
\lim_{\varepsilon \downarrow 0} \frac{1}{\varepsilon} \left( T(\mu_{N,t+\varepsilon}) - T(\mu_{N,t}) \right) = \lim_{\varepsilon \downarrow 0} \frac{1}{\varepsilon} \left( \int T^{-1}(\sigma_{V_N}) \rho_{N,t+\varepsilon}(\sigma_{V_N}) \alpha \otimes N(d\sigma_{V_N}) - \int T^{-1}(\sigma_{V_N}) \rho_{N,t}(\sigma_{V_N}) \alpha \otimes N(d\sigma_{V_N}) \right)
$$

$$
= \frac{1}{Z} \lim_{\varepsilon \downarrow 0} \frac{1}{\varepsilon} \left( \int T^{-1}(\sigma_{V_N}) \rho_{N,t}(\sigma_{V_N}) \alpha \otimes N(d\sigma_{V_N}) - \int T^{-1}(\sigma_{V_N}) \rho_{N,t+\varepsilon}(\sigma_{V_N}) \alpha \otimes N(d\sigma_{V_N}) \right)
$$

$$
= \frac{1}{Z} \sum_{i=1}^{N} \lim_{\varepsilon \downarrow 0} \frac{1}{\varepsilon} \left( \int T^{-1}(\sigma_{V_N}) \int T^{-1}(\sigma') \rho_{N,t}(\sigma_{V_N}) \alpha \otimes N(d\sigma_{V_N}) - \int T^{-1}(\sigma_{V_N}) \int T^{-1}(\sigma') \rho_{N,t+\varepsilon}(\sigma_{V_N}) \alpha \otimes N(d\sigma_{V_N}) \right)
$$

$$
= \sum_{i=1}^{N} \left( c_{\mu_{N},t}(\sigma'_{V_N} - 1, \sigma_{V_N}) T(\mu_{N,t})(\sigma'_{V_N} - 1) - c_{\mu_{N},t}(\sigma'_{V_N}, \sigma_{V_N} + 1) T(\mu_{N,t})(\sigma'_{V_N}) \right)
$$

$$
= T(\mu_{N,t})(Q_{\mu_{N},t})
$$

Plugging in for $\rho$ the Gibbs density for a rotation-invariant potential, the rates take the time-independent form

$$
c_{\mu_{N},t}(\sigma'_{V_N}, \sigma_{V_N} + 1_i) = \frac{\int T^{-1}(\sigma'_{V_N}) e^{-N\Phi(\frac{1}{\alpha} \delta_{\sigma'_{V_N}} + \frac{N-1}{N}L_{N-1}(\sigma_{V_N}))} \alpha \otimes N\setminus\{i\}(d\sigma_{V_N})}{\int T^{-1}(\sigma_{V_N}) e^{-N\Phi(L_N(\sigma_{V_N}))} \alpha \otimes N(d\sigma_{V_N})} \tag{2.2}
$$

and $T(\mu_{N,N})(Q_{\mu_{N},N} g) = 0$ for all discrete observables $g$. Hence $T(\mu_{N,N})$ is invariant under $Q_{\mu_{N},N}$. Notice one can rewrite the rates as

$$
c_{\mu_{N},t}(\sigma'_{V_N}, \sigma_{V_N} + 1_i) = \frac{\mu_{N-1}[\sigma'_{V_N}] e^{-N\Phi(\frac{1}{\alpha} \delta_{\sigma'_{V_N}} + \frac{N-1}{N}L_{N-1}(\sigma_{V_N}))]}{\mu_{N-1}[\sigma_{V_N}] e^{-N\Phi(\frac{1}{\alpha} \delta_{\sigma_{V_N}} + \frac{N-1}{N}L_{N-1}(\sigma_{V_N}))} \alpha(d\sigma_{V_N})}
$$

where $\mu_{N-1}[\sigma'_{V_N}]$ stands for the Gibbs measure conditioned to the set $T^{-1}(\sigma'_{V_N})$. In fact only empirical distributions of the coarse-grained spin variables $L_{N-1}(\sigma'_{V_N})$ and the state of $\sigma'_{i}$ come into play. Thus by writing $\nu' \in \mathcal{P}(\{1, \ldots, q\})$ for a possible empirical measure $L_N$ with $\nu'(k) > 0$ we can again re-express the rates as

$$
c_{N}^{emp}(k, \nu') = \frac{\nu'[\nu'] e^{-N\Phi(\frac{1}{\alpha} \delta_{\nu'} + \frac{N-1}{N}L_{N-1}(\nu'))}}{\nu'[\nu] e^{-N\Phi(\frac{1}{\alpha} \delta_{\nu} + \frac{N-1}{N}L_{N-1}(\nu))} \alpha(d\sigma)} \tag{2.3}
$$

where we now dropped the indication for the Gibbs measure in $c_{N}^{emp}$ and $\nu' = \frac{N}{N-1} \nu - \frac{1}{N-1} \delta_k$. Notice for large $N$, $\nu' \approx \nu$. 

Synchronization for discrete mean-field rotators

We can now lift the whole process to the level of empirical distributions. The resulting generator is given in (1.5).

**Proof of Corollary 1.2**: We have to check $T(\mu_{\Phi,N})((Q^{\text{emp}}_N f) \circ L_N) = 0$ for all bounded measurable functions $f : \mathcal{P}\{1, \ldots, q\} \mapsto \mathbb{R}$.

$$T(\mu_{\Phi,N})((Q^{\text{emp}}_N f) \circ L_N)$$

$$= \sum_{\sigma_{V_N}} T(\mu_{\Phi,N})(\sigma_{V_N}^i) N \sum_{k=1}^{q} L_N(\sigma_{V_N}^i(k)c^{\text{emp}}_N(k, L_N(\sigma_{V_N}^i) \times$$

$$\left( f(L_N(\sigma_{V_N}^i) + \frac{1}{N}(\delta_{k+1} - \delta_k)) - f(L_N(\sigma_{V_N}^i)) \right)$$

$$= \sum_{\sigma_{V_N}} T(\mu_{\Phi,N})(\sigma_{V_N}^i) \sum_{i=1}^{N} \sum_{k=1}^{q} \delta_{\sigma_{V_N}^i}(k)c^{\text{emp}}_N(k, L_N(\sigma_{V_N}^i) \times$$

$$\left( f(L_N(\sigma_{V_N}^i) + \frac{1}{N}(\delta_{k+1} - \delta_k)) - f(L_N(\sigma_{V_N}^i)) \right)$$

$$= \sum_{\sigma_{V_N}} T(\mu_{\Phi,N})(\sigma_{V_N}^i) \sum_{i=1}^{N} c_{\mu_{\Phi,N}}(\sigma_{V_N}^i, \sigma_{V_N}^i + 1) \left( f(L_N(\sigma_{V_N}^i + 1)) - f(L_N(\sigma_{V_N}^i)) \right)$$

$$= T(\mu_{\Phi,N})(Q_{\mu_{\Phi,N}}(f \circ L_N)).$$

But $T(\mu_{\Phi,N})(Q_{\mu_{\Phi,N}}(f \circ L_N)) = 0$ since $T(\mu_{\Phi,N})$ is invariant for $Q_{\mu_{\Phi,N}}$. □

### 2.2 Infinite-volume rates: Existence and non-existence

Let us prepare the proof of Theorem 1.3 by the following lemma.

**Lemma 2.1.** For any differentiable mean-field interaction potential $\Phi : \mathcal{P}(S^1) \mapsto \mathbb{R}$ with

$$\sup_{s, t \in S_k} |d_p\Phi(\delta_s - \delta_t) - d_p\Phi(\delta_s - \delta_t)| \leq C(q)\|\bar{\mu} - \mu\|$$

where $C(q) \downarrow 0$ for $q \uparrow \infty$ monotonically, there is an integer $q(\Phi)$ such that for all $q \geq q(\Phi)$ the free energy minimization problem $\nu \mapsto \Phi(\nu) + S(\nu|\alpha)$ has a unique solution in the set $\{\nu \in \mathcal{P}(S^1) | T(\nu) = \nu'\}$ for any $\nu' \in \mathcal{P}\{1, \ldots, q\}$.

We call this solution $\nu'$. The proof follows a line of arguments given in [17] in the lattice situation.

**Proof of Lemma 2.1:** Let $\mu$ be a solution of the constrained free energy minimization problem $\nu \mapsto \Phi(\nu) + S(\nu|\alpha)$ with $T(\mu) = \nu'$ and $\bar{\mu}$ be a solution of the constrained free energy minimization problem $\nu \mapsto \Phi(\nu) + S(\nu|\alpha)$ with $\Phi$ being another continuously differentiable mean-field interaction potential and $T(\bar{\mu}) = \nu'$. Using Lagrange multipliers to characterize the constrained extremal points of the free energy we find $\mu$ and $\bar{\mu}$ must have the form

$$\mu(ds|S_k) = \frac{1}{\int_{S_k} \exp(-d_p\Phi(\delta_s - \mu))\alpha(ds)} \gamma_k(ds|\mu) =: \gamma_k(ds|\mu)$$

$$\bar{\mu}(ds|S_k) = \frac{1}{\int_{S_k} \exp(-d_p\Phi(\delta_s - \mu))\alpha(ds)} \gamma_k(ds|\bar{\mu}) =: \tilde{\gamma}_k(ds|\bar{\mu}).$$

Let us estimate for a bounded measurable function $f$

$$|\mu(f|S_k) - \bar{\mu}(f|S_k)| \leq |\gamma_k(f|\mu) - \gamma_k(f|\bar{\mu})| + |\gamma_k(f|\bar{\mu}) - \tilde{\gamma}_k(f|\bar{\mu})|. \quad (2.5)$$
Synchronization for discrete mean-field rotators

With \( \|\alpha_1 - \alpha_2\| := \max_{f} \text{bounded, measurable} |\alpha_1(f) - \alpha_2(f)|/\delta(f) \) denoting the total-variation distance of probability measures where \( \delta(f) := \sup_{x,y} |f(x) - f(y)| \) is the variation of a bounded function we have

\[
|\gamma_k(f|\bar{\mu}) - \bar{\gamma}_k(f|\bar{\mu})| \leq \delta(f)\|\gamma_k(\cdot|\bar{\mu}) - \bar{\gamma}_k(\cdot|\bar{\mu})\| =: \delta(f)b(\bar{\mu}).
\]

For the first term in (2.5) we similarly write

\[
|\gamma_k(f|\mu) - \gamma_k(f|\bar{\mu})| \leq \delta(f)\|\gamma_k(\cdot|\mu) - \gamma_k(\cdot|\bar{\mu})\|.
\]

Now let \( u_1(s) := d_{\mu} \Phi(\delta_s - \mu), u_0(s) := d_{\mu} \Phi(\delta_s - \bar{\mu}), v := u_1 - u_0 \) and \( u_1 := u_0 + tv \). Define \( h^t_k := \exp(u_1)1_{S_k}/\alpha(\exp(u_1)1_{S_k}) \) and \( \lambda^t_k(ds) := h^t_k(s)\alpha(ds). \) Then we have

\[
\begin{align*}
2\|\gamma_k(\cdot|\mu) - \gamma_k(\cdot|\bar{\mu})\| &= 2\|\lambda^t_k - \lambda_0^t\| \\
&= \int_0^1 dt\lambda^t_k([v - \lambda^t_k(v)]) \\
&\leq \int_0^1 dt \int S_k(dx) \int S_k(dy) |v(x) - v(y)| \\
&\leq \sup \int_{-r}^r \lambda(dx) \int_{-r}^r \lambda(dy)|x - y| \\
&\leq C(\lambda)\|\mu - \bar{\mu}\| \\
&\leq C(q) \|\mu(S_k) - \bar{\mu}(S_k)\| \\
&\leq \sup_{i \in \{1, \ldots, q\}} \|\mu(S_k) - \bar{\mu}(S_k)\| + b(\bar{\mu}).
\end{align*}
\]

where the supremum is over all probability measures on the interval \([-r, r]\) with \( 2r := \sup_{s,t \in S_k} |d_{\mu} \Phi(\delta_s - \delta_t) - d_{\mu} \Phi(\delta_s - \delta_t)| \). By assumption we have

\[
2r \leq C(q)\|\mu - \bar{\mu}\| \leq C(q) \sup_{i \in \{1, \ldots, q\}} \|\mu(S_i) - \bar{\mu}(S_i)\| \\
(2.7)
\]

with \( C(q) \downarrow 0 \) for \( q \uparrow \infty \) monotonically. Using the fact, that for all probability measures \( p \) on \([-r, r]\) we have \( \int p(dx) \int p(dy)|x - y| \leq r \) and (2.7) we can thus find \( q(\Phi) \) such that

\[
\|\gamma_k(\cdot|\mu) - \gamma_k(\cdot|\bar{\mu})\| \leq C(q(\Phi)) \sup_{i \in \{1, \ldots, q\}} \|\mu(S_i) - \bar{\mu}(S_i)\|
\]

with \( C(q(\Phi)) < 1 \). Hence for all \( q \geq q(\Phi) \)

\[
\|\mu(S_k) - \bar{\mu}(S_k)\| \leq \delta(f)(C(q) \sup_{i \in \{1, \ldots, q\}} \|\mu(S_i) - \bar{\mu}(S_i)\| + b(\bar{\mu})).
\]

Taking the supremum over \( f \) and over \( k \) we have

\[
\sup_{k \in \{1, \ldots, q\}} \|\mu(S_k) - \bar{\mu}(S_k)\| \leq \frac{1}{1 - C(q)}b(\bar{\mu}).
\]

Now for \( \bar{\Phi} = \Phi \) of course \( b(\bar{\mu}) = 0 \) and thus \( \mu = \bar{\mu} \). \( \square \)

**Proof of Theorem 1.3:** We show for \( N \uparrow \infty, c_{N}^{emp}(k, \nu') \rightarrow c(k, \nu') \) for all \( k \in \{1, \ldots, q\} \) and \( \nu' \in \mathcal{P}(\{1, \ldots, q\}) \). For the nominator in the definition of \( c_{N}^{emp}(k, \nu') \) we have

\[
\begin{align*}
\mu_{\Phi, N-1}^{emp}(\cdot|\nu') &\left( e^{-N\Phi\left(\frac{1}{N} \frac{d_{\nu' \otimes \nu'} - L_{N-1}}{x} + N-1\Phi(L_{N-1})\right)} \Phi(L_{N-1}) \right) \\
&=: \frac{1}{Z_1} \int e^{-N\Phi\left(\frac{1}{N} \frac{d_{\nu' \otimes \nu'} - L_{N-1}}{x} + N-1\Phi(L_{N-1})\right)} 1_{T(L_{N-1})=\nu' \otimes \nu'} d\alpha \otimes N \mathbb{1}\i
\end{align*}
\]

Synchronization for discrete mean-field rotators

where $Z_1$ is a normalization constant and we used Taylor expansion of the interaction potential w.r.t. measures. For the limit $N \to \infty$ we can employ Varadhan’s lemma together with Sanov’s theorem and Lemma 2.1 and write

$$
\frac{1}{Z_1} \int e^{-N \Phi(L_{N-1}) - d_{v_{N-1}} \Phi(\delta_{x y} - L_{N-1}) + o(\frac{1}{N})} L_{N-1} = \nu, d_{\alpha \otimes N \setminus 1} \to \frac{1}{Z_2} e^{-d_{\nu' \Phi}(\delta_{x y} - \nu')}.
$$

The condition $q \geq q(\Phi)$ by Lemma 2.1 ensures, that on the set $\{ \nu \in \mathcal{P}(S^1) | T(\nu) = \nu' \}$ there exists indeed a unique minimizer of the free energy given by $\nu'$.

Using the same arguments for the denominator of $c_N^{emp}(k, \nu')$ the normalization constants cancel and we arrive at $c(k, \nu')$.

\[ \square \]

**Proof of Theorem 1.4:** The first part of the theorem is an application of Lemma 2.1. However we can use the special structure of the scalar product interaction to specify the constant $C(q(\Phi))$. Indeed, using the notation in the proof of Lemma 2.1, from (2.6) we get

$$
\| \gamma_k(\cdot | \mu) - \gamma_k(\cdot | \bar{\mu}) \| \leq \frac{1}{4} \sup_{s, t \in S_k} | d_{\mu} \Phi(\delta_s - \delta_t) - d_{\bar{\mu}} \Phi(\delta_s - \delta_t) |
$$

where $d_{\mu} \Phi(\delta_s - \delta_t) = -\beta(\int \mu(d\omega)e_{x, s} - e_t)$. We have

$$
\sup_{s, t \in S_k} | \int (\bar{\mu}(d\omega) - \mu(d\omega))(e_{x, s} - e_t) | \leq \sup_{s, t \in S_k} \sup_{l \in \{1, \ldots, q\}} | \int (\bar{\mu}(d\omega) - \mu(d\omega))(e_{x, s} - e_t) | \leq \sup_{s, t \in S_k} \sup_{l \in \{1, \ldots, q\}} | (e_{x, s} - e_t) || | (\bar{\mu}(\cdot | S_l) - \mu(\cdot | S_l)) | \leq 4 \sin^2(\frac{\pi}{q}) \sup_{l \in \{1, \ldots, q\}} || | (\bar{\mu} - \mu)(\cdot | S_l) |
$$

where the trigonometric bound follows from Cauchy-Schwartz’s inequality and $\sup_{x, y \in S_l} || e_{x} - e_y ||_2 \leq 2 \sin(\frac{\pi}{q})$. By assumption $\beta \sin^2(\frac{\pi}{q}) < 1$ and thus the first result follows.

Notice, in case of the standard scalar product potential we have

$$
-d_{\nu' \Phi}(\delta_{x y} - \nu') = \beta(\int \nu'(d\omega)e_{x, y}) + \beta(\int \nu'(d\omega)e_{x, y} - \int \nu'(d\omega)e_{x, y})
$$

where the second summand is independent of the integration in the denominator of the rates and thus cancels. Using the notation $M_\beta(\nu') = \int \nu'(d\omega)e_{x, y}$ we arrive at the definition of the rates (1.6).

\[ \square \]

To complement the above criterion on the fineness of discretization in order to have unique constrained free energy minimizer for the rotator model, let us consider an equivalent of a checkerboard configuration on the lattice. Namely the measure with equal weight on segments facing in opposite directions. This will lead to a criterion for non-uniqueness of the constrained minimizers. For convenience take $q$ even. We condition on $\nu = \frac{1}{2}(\delta_1 + \delta_{-1})$, then from (2.4) we know for a constrained minimizers $\nu'$ we have

$$
M_\beta(\nu') = \sum_k \nu'(k) \int \nu'(d\omega|S_k)e_{x, y} = \sum_k \nu'(k) \int \frac{S_k e_{x, y} \exp(\beta(e_{x, y}, M_\beta(\nu')) \alpha(d\omega)}{\int S_k \exp(\beta(e_{x, y}, M(\nu')) \alpha(d\omega)}.
$$

Synchronization for discrete mean-field rotators

Note, this equation is often referred to the mean-field equation. By symmetry and under suitable coordinates this fixed point equation becomes one-dimensional and reads

\[ m = \frac{\int_{-\pi}^{\pi} \sin(\omega) \exp(\beta m \sin(\omega)) \alpha(d\omega)}{\int_{-\pi}^{\pi} \exp(\beta m \sin(\omega)) \alpha(d\omega)} =: F_q(\beta m). \]  

(2.10)

Since \( F_q \) is concave, the equation (2.10) has no non-trivial fixed point if \( \frac{d}{dm} F_q(m) < 1 / \beta \), i.e. \( \beta(\frac{1}{2} - \frac{q}{2\pi} \sin(\frac{2\pi}{q})) < 1 \). On the other hand if

\[ \beta \left( 1 - \frac{q}{2\pi} \sin\left( \frac{2\pi}{q} \right) \right) > 2 \]  

(2.11)

there must be a non-trivial fixed point since \( F \) is bounded and continuous. In other words if (2.11) holds, there are two distinct measures \( \nu^\nu \neq \nu' \). In particular \( \int \nu^\nu(d\omega)e_\omega = - \int \nu'(d\omega)e_\omega \neq 0 \) and \( \Psi(\nu^\nu) = \Psi(\nu') \) because of symmetry. Hence in the regime (2.11) we just provided an example were the constrained model has multiple Gibbs measures and hence the limiting rates in Theorem 1.3 can not be defined for all \( \nu' \).

2.3 Infinite-volume rotation dynamics

Let us in the sequel specify to the rotator model with scalar product potential and its discretization, assumed to be in the parameter regime \( \beta > 2 \) and \( \beta \sin^2\left( \frac{\pi}{q} \right) < 1 \).

Lemma 2.2. The non-linear system of ordinary differential equations given in Theorem 1.5 with rates (1.6) is uniquely solvable globally in time.

Notice the ODE (1.8) in Theorem 1.5 can be interpreted as inflow from below into state \( k \) minus outflow in the direction \( k + 1 \).

Proof of Lemma 2.2: For a given initial measure \( \nu^0 \) the system (1.7) is uniquely solvable locally in time by the Picard-Lindelöf theorem (see for example \([2]\)). Indeed, we show Lipschitz continuity of (1.8) as a function of \( \nu' \) w.r.t. the total-variation distance. It suffices to show Lipschitz continuity for \( \nu' \mapsto \nu^\nu \) since (1.8) is a composition of Lipschitz continuous functions of \( \nu^\nu \). First note

\[ \|\nu^\nu - \nu^\nu'\| \leq \sup_{k \in \{1, \ldots, q\}} \|\nu^\nu(\cdot)\mid S_k - \nu^\nu'(\cdot)\mid S_k\| + \|\nu' - \nu'\|. \]

Introducing \( \gamma_k(ds|\nu^\nu') \) as defined in (2.4) we can further write for a bounded measurable function \( f \)

\[ |\nu^\nu(f|S_k) - \nu^\nu'(f|S_k)| = |\gamma_k(f) \sum_{l=1}^{q} \nu'(l) \nu^\nu'(\cdot)|S_l\) - \nu^\nu'(\cdot)|S_l\)\]  

\[ \leq \delta(f) \left( \frac{\beta \sin^2\left( \frac{\pi}{q} \right)}{q} \sup_{l \in \{1, \ldots, q\}} \|\nu^\nu'(\cdot)\mid S_l - \nu^\nu'(\cdot)\mid S_l\| \right.
\]

\[ \left. + \|\gamma_k(\cdot) \sum_{l=1}^{q} \nu'(l) \nu^\nu'(\cdot)|S_l\) - \gamma_k(\cdot) \sum_{l=1}^{q} \nu'(l) \nu^\nu'(\cdot)|S_l\)\| \right) \]

Synchronization for discrete mean-field rotators

where we used (2.8) and (2.9) for the first summand. For the second summand we have
\[
\|\gamma_k(\cdot) \sum_{l \in \{1, \ldots, q\}} \nu'(l) \nu''(\cdot | S_l) - \gamma_k(\cdot) \sum_{l \in \{1, \ldots, q\}} \tilde{\nu}'(l) \tilde{\nu}''(\cdot | S_l)\| \\
\leq \frac{\beta}{4} \sup_{s,t \in S_k} \left| \sum_{l=1}^q \nu'(l) \int \nu''(\cdot | S_l)(d\omega) e_{\omega} - \sum_{l=1}^q \tilde{\nu}'(l) \int \tilde{\nu}''(\cdot | S_l)(d\omega) e_{\omega}, e_s - e_t \right| \\
\leq \frac{\beta}{4} \sup_{s,t \in S_k} \sup_{1 \leq i,j \leq q} \left| \int \nu''(\cdot | S_i)(d\omega) e_{\omega} - \int \tilde{\nu}''(\cdot | S_j)(d\omega) e_{\omega}, e_s - e_t \right| \|\nu' - \tilde{\nu}'\| \\
\leq \frac{\beta}{2} \sup_{s,t \in S_k} \|e_s - e_t\| \|\nu' - \tilde{\nu}'\| = \beta \sin(\frac{\pi}{4}) \|\nu' - \tilde{\nu}'\|
\]
where we used (2.6) in the first inequality. Thus taking the supremum over \( f \) and \( k \) and using the fact, that we are in the right parameter regime \( \beta \sin^2(\frac{\pi}{4}) < 1 \), we have
\[
\sup_{k \in \{1, \ldots, q\}} \|\nu''(\cdot | S_k) - \nu''(\cdot | S_k)\| \leq C \|\nu' - \tilde{\nu}'\|.
\]
But this is Lipschitz continuity, implying local existence.

Solutions also always exist globally: If \( \nu'(k) = 0 \) for some \( k \), we have \( \frac{d}{dk} \nu'(k) = c(k-1, \nu')(k-1) \geq 0 \). In other words, if a solution is on the boundary of the simplex, the vector field forces the trajectory back inside the simplex.

**Remark 2.3.** The above lemma in particular proves, that the so called second-layer mean-field specification \( \gamma'(k|\nu') := \int_{S_k} \exp(\beta(M_k(\nu'), e_{\omega})) \rho(\omega) d\omega \) is continuous w.r.t the boundary entry \( \nu' \). This is the defining property for a system after coarse-graining to be called Gibbs (see for example [33, 34, 29]).

**Proof of Theorem 1.5:** We use the Feng-Kurtz scheme as presented in [19, 14, 41] to show convergence on the level of trajectories. The Feng-Kurtz scheme provides us with a large deviation rate function that can be expressed as the integral of the Legendre transform of the generator of the exponential semigroup defined by the dynamics. This generator can be associated to the so-called Feng-Kurtz Hamiltonian, and the rate function to the integral of a Lagrangian.

The Feng-Kurtz Hamiltonian for the generator \( Q_N^{emp} \) reads
\[
\mathcal{H}(\nu', f) = \sum_{k=1}^q \nu'(k) c(k, \nu') \left( e^{\delta_k(\nu_\nu' - \nu')} - d_{\nu'}(\delta_k - \nu') + 1 \right)
\]
where \( f : \mathcal{P}(\{1, \ldots, q\}) \to \mathbb{R} \) is a differentiable observable and we used the convergence of the rates from Theorem 1.4. This Hamiltonian is of the form as presented in [19] Section 10.3. with \( h(\nu') := F(\nu') \) and \( \eta(\nu', \delta_{k+1} - \delta_k) := \nu'(k)c(k, \nu') \). Following the roadmap of [19] we verify (using references as in [19]):

1. \( X_n \) is exponentially tight in the path space by Theorem 4.1. since
\[
\mathbb{E}(e^{N\lambda_n^2} | X_{t+1}^n - X_0^n | | F_N) \leq \mathbb{E}(e^{\lambda_0^2(N K_D)}) = e^{N K_D (e^\lambda - 1)}
\]
where \( \text{Pois}(r) \) stands for a Poisson random variable with intensity \( r \), \( K := \sup_{\nu \in \mathcal{P}(\{1, \ldots, q\})} \mathbb{E} \sum_{k \in \{1, \ldots, q\}} e^{\sum_{\nu} C_N^{emp}(k, \nu')} \) and \( F_N = \sigma((X_k)_0^N \leq \delta) \). In particular \( K_D (e^\lambda - 1) = 0 \) and thus criterion b) of Theorem 4.1. is satisfied.

2. The comparison principle holds for the generator \( \mathcal{H} \) (ensuring the existence of the so-called exponential semigroup corresponding to \( \mathcal{H} \)) since the conditions of Lemma 10.12. are satisfied. In particular we used the Lipschitz continuity of \( F(\nu') \) from our Lemma 2.2. This property ensures existence of a LDP for the finite-dimensional distributions of the process.
Synchronization for discrete mean-field rotators

Further since also (10.18) in [19] is satisfied, Theorem 10.17. in [19] gives the LDP on the level of paths implicitly via the exponential semigroup.

In order to get a nice variational representation of the large deviation rate function we follow the Feng-Kurtz scheme and calculate the cost function in form of the Lagrangian of $H$ for the measure $\nu'$ and the velocity $u'$ (a zero-weight signed measure on $\{1, \ldots, q\}$) as in Lemma 10.19. in [19]

$$L(\nu', u') := \sup_{p \in \mathbb{R}^q} \left( \langle p, u' \rangle - \sum_{k=1}^q \nu'(k)c_L(k, \nu')(e^{p(k+1)-p(k)} - 1) \right) \geq 0.$$ 

Let $P^N_{\nu_0}$ denote the law of the Markov process $Q^\text{emp}$ started in $\nu_0$, then by Theorem 10.22. in [19] we have

$$P^N_{\nu_0} \left( (t)_{t \in [0, T_f]} \approx (\nu'_t)_{t \in [0, T_f]} \right) \approx \exp \left( -N \int_0^{T_f} L(\nu'_t, \frac{d}{dt}\nu'_t)dt \right)$$

where the approximation signs should be understood in the sense of the LDP with the Skorokhod topology on the space of càdlàg paths. In fact by [19] Theorem 4.14 the LDP even holds in the uniform topology.

To obtain the LLN we need to show $L(\nu'_t, \frac{d}{dt}\nu'_t) = 0$ if $\frac{d}{dt}\nu'_t$ is given by (1.7). But this is true: The Lagrangian for (1.7) reads

$$L(\nu'_t, \frac{d}{dt}\nu'_t) = \sup_{p} \left( \langle p, \frac{d}{dt}\nu'_t \rangle - \sum_{k=1}^q \nu'_t(k)c(k, \nu'_t)(e^{p(k+1)-p(k)} - 1) \right) = \sup_{p} J(p)$$

(2.12)

with $\frac{\partial^2}{\partial p \partial \nu_t} J(p) = \nu'_t(l-1)c(l-1, \nu'_t)(1 - e^{p(l-1)-p(l-1)}) - \nu'_t(l)c(l, \nu'_t)(1 - e^{p(l-1)-p(l)})$. In case $\nu'_t(k) = 0$ for some $l \in \{1, \ldots, q\}$ and $p^*$ realizing the supremum in (2.12) we have $\nu'_t(k)c(k, \nu'_t)(1 - e^{p^*(k+1)-p^*(k)}) = 0$ for all $k \in \{1, \ldots, q\}$ and since $c(k, \nu'_t) > 0$ in particular $p^*(k+1) = p^*(k)$ whenever $\nu'_t(k) > 0$. Thus $L(\nu'_t, \frac{d}{dt}\nu'_t) = 0$. In case $\nu'_t(k) > 0$ for all $k \in \{1, \ldots, q\}$, $J$ is strictly concave away from any constant vector $p = (c, \ldots, c)^T \in \mathbb{R}^q$, to be precise

$$\langle z, \frac{\partial^2}{\partial p(l) \partial \nu_t(l)} J(p) \rangle_i = -\sum_{k=1}^q \nu'_t(k)c(k, \nu'_t)e^{p(k+1)-p(k)}(z_{k+1} - z_k)^2$$

for all $q$-dimensional vectors $z$, and thus $J(0)$ is the global maximum of $J$. Hence $L(\nu'_t, \frac{d}{dt}\nu'_t) = 0$. Since $L(\nu'_t, \cdot)$ is strictly convex as a Legendre transform of the strictly convex Feng-Kurtz Hamiltonian $H$, the flow (1.7) is the unique dynamics such that $\int_0^{T_f} L(\nu'_t, \frac{d}{dt}\nu'_t)dt = 0$. But that means, according to the LDP, that (1.7) is the unique limiting dynamics as $N \to \infty$. \hfill \Box

**Remark 2.4.** If one is only interested in the (weak) LLN for $X_n$, one can also apply Theorem 2 of [39], with the minor alteration, that our rates are $N$-dependent but convergent. The proof of the result uses martingale representation to derive tightness of $(P^N_{\nu_0})_{N \in \mathbb{N}}$ (in the pathspace equipped with the Skorokhod topology). The uniqueness of the limiting (deterministic) process is shown by a coupling argument. For the sake of accessibility we compare the notation in [39] with ours: $\gamma_n(k) := \delta_1(k)$, $A(k, y, \nu') := c^\text{emp}_N(k, \nu')$, all given topologies on $\mathcal{P}\{\{1, \ldots, q\}\}$ are equivalent, the Lipschitz condition (B4) is satisfied since $\nu' \mapsto c^\text{emp}_N(k, \nu')$ is a composition of Lipschitz continuous functions (where we have to use Lemma 2.2), (B3), (B2) and (B1) are trivially satisfied.

EJP 19 (2014), paper 14. ejp.ejpecp.org
3 Properties of the flow

In [30] one of the main results states the existence of a unique translation-invariant invariant measure for the rotation dynamics combined with a Glauber dynamics on the lattice, which is not the long-time limit of all starting measures. This is done by identifying a set of starting measures, namely the set of extremal translation-invariant Gibbs measures of a discretized version of the XY model, which is not attracted to the invariant measure. Further results about attractivity of the rotation dynamics alone for general starting measures seemed to be difficult on the lattice.

In this section we reproduce the equivariance properties of the discretization map for the dynamical system. Further we investigate attractivity properties of the flow.

Before we start let us note, that (as in the lattice situation) the commutator (in the form of the Lie bracket) of the rotation dynamics and the corresponding Glauber dynamics vanishes on $G'$. In general there is no reason to believe that the two dynamics do commute.

In the sequel we denote $\nu_t'$ a probability measure on $\{1, \ldots, q\}$ at time $t$ under the rotation dynamics (1.7).

3.1 Closed orbit and equivariance of the discretization map

Proof of Theorem 1.6: For $\nu \in G(\Phi)$ we have $T(\nu) \in G'$ by the contraction principle. Further for $\nu' \in G'$ we have

$$\inf_{\nu} \Psi(\nu) = \inf_{\nu' \in T(\nu)} \Psi(\nu') = \Psi' = \Psi(\nu'),$$

hence $\nu' \in G(\Phi)$ and we have established a one-to-one correspondence between $G'$ and $G(\Phi)$.

Let us verify the dynamical aspects of the diagram. Let $\nu_t \in G(\Phi)$ and compute the derivative (in analogy to Proposition 1.1) and note that indeed the left-sided and the right-sided derivatives coincide

$$\frac{d}{dz} \Psi_{\nu_t}(z) = \frac{d}{dz} \Psi_{T(\nu_t)}(z) = \frac{d}{dz} \Psi_{T(\nu_t)}(z).$$

By Lemma 2.2, the differential equation (1.7) is uniquely solvable globally in time. Since $(T(\nu_t))_{t \geq 0}$ is a trajectory in $P([1, \ldots, q])$ solving the differential equation we have $T(\nu_{s+t}) = \varphi(s, T(\nu_t))$ for all $s, t \geq 0$.

Note: One can also show higher differentiability of the flow with respect to the initial condition. Strong enough differentiability of $F$ would ensure that. This again would be guaranteed by strong enough differentiability of $\nu' \mapsto M_S(\nu')$. One can employ an implicit function theorem applied to the mean-field equation to get that kind of regularity. Unfortunately a price to pay could a priori be the assumption of an unspecified maybe large $q$, so some additional technical work would be needed.

In the sequel we will often refer to $G'$ as the periodic orbit of the flow $(\varphi_t)_{t \geq 0}$. 

3.2 Attractivity of the closed orbit via free energy

**Lemma 3.1.** The time derivative of the free energy on \( \mathcal{P}([1, \ldots, q]) \) reads

\[
\frac{d}{dt}|_{t=0} \Psi(\phi(t, \nu')) = \sum_{k \in \{1, \ldots, q\}} \frac{e^{\beta(c_{x, k} M_{\beta}(\nu'))}}{\int_{S_k} e^{\beta(c_{x, k} M_{\beta}(\nu'))} \alpha(d\omega)} \nu'(k) \log \frac{\nu'(k + 1) \int_{S_k} e^{\beta(c_{x, k} M_{\beta}(\nu'))} \alpha(d\omega)}{\nu'(k) \int_{S_{k+1}} e^{\beta(c_{x, k} M_{\beta}(\nu'))} \alpha(d\omega)}. \tag{3.2}
\]

**Proof of Lemma 3.1:** First note, if \( \nu' \in \mathcal{G}' \) or \( \nu' = \frac{1}{q} \sum_{k=1}^q \delta_k \) we have \( \nu'(k) = K \int_{S_k} e^{\beta(c_{x, k} M_{\beta}(\nu'))} \alpha(d\omega) \) and hence \( \frac{d}{dt}|_{t=0} \Psi(\phi(t, \nu')) = 0 \). For any distribution with no weight on at least one \( k \in \{1, \ldots, q\} \), the r.h.s of (3.2) is minus infinity.

Let us change the perspective and assume \( \beta M_{\beta}(\nu') = x \in \mathbb{R}^2 \) to be given instead of \( \nu' \). Let \( \Gamma_k : \mathbb{R}^2 \rightarrow \mathbb{R}^2, \Gamma_k(x_1, x_2) = \frac{\int_{S_k} \exp(\{c_{x, k}(x_1, x_2)\}) \alpha(d\omega)}{\int_{S_k} \exp(\{c_{x, k}(x_1, x_2)\}) \alpha(d\omega)} \) and define \( \Lambda_x := \{\{\lambda_1, \ldots, \lambda_q\} \in \mathbb{R}^q | \sum_{k} \lambda_k \Gamma_k(x) = x\} \) the space of unnormalized measures such that their corresponding probability measures \( (\lambda_k/\|\lambda\|_t)_{k \in \{1, \ldots, q\}} \) have magnetization \( x/\beta \), in particular \( \|\lambda\|_t = \beta \). Let us rewrite the free energy and prove instead of \( \frac{d}{dt}|_{t=0} \Psi(\phi(t, \nu')) \leq 0 \),

\[
0 \geq \sum_{k \in \{1, \ldots, q\}} \frac{e^{(c_{x, k} - x)}}{\int_{S_k} \exp(c_{x, k}) \alpha(d\omega)} \lambda(k) \log \frac{\lambda(k + 1) \int_{S_k} e^{(c_{x, k})} \alpha(d\omega)}{\lambda(k) \int_{S_{k+1}} e^{(c_{x, k})} \alpha(d\omega)} =: G_x(\lambda_1, \ldots, \lambda_q)
\]

for \( \lambda \in \Lambda_x \). One way to do this is to show that for given \( x \in \mathbb{R}^2 \) the maximum of \( G_x \) under the constraint \( \{\lambda_1, \ldots, \lambda_q\} \in \Lambda_x \) is lower or equal zero. Let us apply Lagrange multipliers \( \alpha_1, \alpha_2 \), then we must solve the following \( q + 2 \) equations

\[
\frac{d}{d\lambda_k} G_x(\lambda_1, \ldots, \lambda_q) + \alpha_1 (\sum_k \lambda_k \Gamma_k(x_1 - x_1) + \alpha_2 (\sum_k \lambda_k \Gamma_k(x_2 - x_2) = 0
\]

\[
\sum_k \lambda_k \Gamma_k(x) = x. \tag{3.3}
\]

The first line of (3.3) reads

\[
\frac{e^{(c_{x, k} - x)}}{\int_{S_k} \exp(c_{x, k}) \alpha(d\omega)} \log \frac{\lambda(k + 1) \int_{S_k} e^{(c_{x, k})} \alpha(d\omega)}{\lambda(k) \int_{S_{k+1}} e^{(c_{x, k})} \alpha(d\omega)} - \frac{e^{(c_{x, k} - x)}}{\int_{S_k} \exp(c_{x, k}) \alpha(d\omega)} e^{(c_{x, k} - (k-1) x)} \lambda(k - 1) \lambda(k) + \alpha_1 \Gamma_k(x_1) + \alpha_2 \Gamma_k(x_2) = 0.
\]

Synchronization for discrete mean-field rotators

Multiplying these equations with $\lambda_k$, summing and applying the constraint condition we have $G_x(\lambda_1, \ldots \lambda_q) + \langle \alpha, x \rangle = 0$ and thus the sign is determined by the Lagrange multipliers. Define $\beta > 0$ such that $\frac{\pi}{\beta} = \int e^{i(\omega \cdot x)} \alpha(d\omega)$ and $\lambda_k := \beta \frac{\int e^{i(\omega \cdot x)} \alpha(d\omega)}{\int e^{i(\omega \cdot x)} \alpha(d\omega)}$ the Gibbs measure for $x$ rescaled with $\beta$. In particular $\sum_k \lambda_k \Gamma_k(x) = x$. First we show $\Lambda := (\lambda_i)_{i \in \{1, \ldots, q\}}$ is an extremal point of $G_x$ under the constraint $\Lambda_x$. Indeed, set $\alpha_1 = x_2$ and $\alpha_2 = -x_1$, then the first $q$ equations in (3.3) read

$$e^{\frac{i \pi x_2}{\beta}(k-1)^2} - e^{\frac{i \pi x_2}{\beta}k^2} + \frac{\int e^{i(\omega \cdot x)} \alpha(d\omega)}{\int e^{i(\omega \cdot x)} \alpha(d\omega)} = \frac{\int e^{i(\omega \cdot x)} \alpha(d\omega)}{\int e^{i(\omega \cdot x)} \alpha(d\omega)} - x_1 \frac{\int e^{i(\omega \cdot x)} \alpha(d\omega)}{\int e^{i(\omega \cdot x)} \alpha(d\omega)}.$$  

But this is zero since $\int e^{i(\omega \cdot x)} \alpha(d\omega) = 0$. Thus we have

$$\int e^{i(\omega \cdot x)} \alpha(d\omega) = \int e^{i(\omega \cdot x)} \alpha(d\omega) = 0.$$  

Secondly we show $G_x$ is concave on $\Lambda_x$, indeed

$$\frac{\partial}{\partial \lambda_k}G_x(\Lambda) = c(k, x) \log \lambda(k + 1) \frac{\int e^{i(\omega \cdot x)} \alpha(d\omega)}{\int e^{i(\omega \cdot x)} \alpha(d\omega)} - c(k, x) + c(k - 1, x) \frac{\lambda(k - 1)}{\lambda(k)}$$

thus the Hessian matrix has non-zero entries only on the diagonal and on the two neighboring diagonals

$$\left( \frac{\partial}{\partial \lambda_k} \right)^2 G_x(\Lambda) = -c(k, x) \frac{c(k - 1, x) \lambda(k - 1)}{\lambda(k)}$$

$$\frac{\partial^2}{\partial \lambda_k \partial \lambda_{k+1}} G_x(\Lambda) = c(k, x) \lambda(k+1) \frac{c(k - 1, x)}{\lambda(k+1)}$$

In order to check definiteness we apply an arbitrary vector $(\lambda_1 z_1, \ldots, \lambda_q z_q)^T$ from both sides, which gives us

$$\sum_{i=1}^q (w_i z_i z_{i+1} + w_{i-1} z_{i+1} z_i - (w_i + w_{i-1}) z_i^2) = \sum_{i=1}^q w_i (2z_i z_{i+1} - (z_i^2 + z_{i+1}^2))$$

where we wrote $w_i := \lambda_i c(i, x)$. Since $z_i z_{i+1} \leq \frac{z_i^2 + z_{i+1}^2}{2}$ the Hessian is negative semidefinite and thus $G_x$ is concave. Hence $\Lambda$ must be a global maximum for $G_x$. To show that the time derivative of $\Psi'$ along trajectories of the flow is indeed strictly negative away from the periodic orbit and the equidistribution we notice, the eigenspace for the eigenvalue zero is $\{ v \in \mathbb{R}^q | v = c \Lambda \}$. Thus the only direction in which $D^2 G_x(\Lambda)$ is not strictly negative is the one along $\Lambda$ but $c \Lambda \notin \Lambda_x$, unless $c = 1$. Hence $\Lambda$ is the only maximum in $G_x$. Since all $G_x$ are disjoint and every probability measure belongs to some $G_x/\beta$, we showed that $\Psi'$ is indeed strictly decreasing away from the periodic orbit and the equidistribution.

Figure 2 shows the time-derivative of the Lyapunov function (3.2) for special values of $\beta$ and $\nu'$. Its negativity away from the equidistribution and the periodic orbit is clearly visible.

**Proof of Theorem 1.8:** Let $K_\varepsilon := \{ \nu' | \inf_{\mu' \in \mathcal{P}} \sum_{k=1}^q |\nu'(k) - \mu'(k)| \geq \varepsilon \}$ then $\frac{d}{dt} |_{s=0} \Psi'(\varphi(s, \nu')) \leq \delta_\varepsilon < 0$ for all $\nu' \in K_\varepsilon$ for some $\delta_\varepsilon < 0$ by compactness of $K_\varepsilon$ and Proposition 1.7. Assume $|\varphi(t, \nu')|_{t \geq 0} \in K_\varepsilon$ for all $t \geq 0$, then for all $s \geq 0$

$$\Psi'(\varphi(t + s, \nu')) - \Psi'(\varphi(t, \nu')) = \int_0^s \frac{d}{dh} \Psi'(\varphi(t + h, \nu')) dh \leq \delta_\varepsilon s.$$  

But $\Psi' \geq 0$ which is a contradiction. Since $\Psi'(\nu') < \Psi(\varepsilon q \sum \delta_k)$ for any Gibbs measure $\nu'$ and by assumption $\Psi'(\nu') \leq \Psi'(\frac{1}{q} \sum \delta_k)$, the flow $\varphi(t, \nu')$ can only leave $K_\varepsilon$ towards the periodic orbit.
3.3 Local stability analysis at the equidistribution via linearization

Recall the definition of the flow

\[
\frac{d}{dt}|_{t=0} \varphi(t, \nu')(k) = c(k-1, \nu')\nu'(k-1) - c(k, \nu')\nu'(k) = F(\nu')(k).
\]

In order to understand local attractivity, we calculate the linearized r.h.s \(dF\). To simplify notation, let us write just \(\frac{d}{de}|_{e=0}\) when we mean \(\frac{d}{de}|_{e=0}\) and \(m_\beta(\nu) := \nu(\cdot|S_k)\) and \(m_\beta(\nu) := \int \nu(d\omega)e_\omega\). For any \(\nu' \in \mathcal{P}\{1, \ldots, q\}\) and zero-weight signed measure \(\rho\) on \(\{1, \ldots, q\}\) we have

\[
dF_{\nu'}(\rho)(k) = \frac{d}{de}F(\nu' + e\rho)(k) = (\frac{d}{de}(c(k - 1, \nu' + e\rho))\nu'(k - 1) - (\frac{d}{de}(c(k, \nu' + e\rho))\nu'(k - 1) - c(k, \nu')\rho(k)
\]

with

\[
\frac{d}{de}c(k, \nu' + e\rho) = \beta c(k, \nu')(e^E e_k - \int_{S_k} e^{\beta(e_\omega, M_\beta(\nu'))} e_\omega \alpha(d\omega), \frac{d}{de}M_\beta(\nu' + e\rho)) = \beta[c(k, \nu')(e^E e_k, \frac{d}{de}M_\beta(\nu')) - e^{\beta(e_\omega, M_\beta(\nu'))}(m_\beta(\nu'_k), \frac{d}{de}M_\beta(\nu' + e\rho))].
\]

To compute the derivative \(\frac{d}{de}M_\beta(\nu' + e\rho)\), we use the 2q-dimensional mean-field equation and apply the implicit function theorem. We have

\[
\frac{d}{de}M_\beta(\nu' + e\rho) = \sum_k \nu'(k) \frac{d}{de}m_\beta(\nu'_k + e\rho) + \sum_k \rho(k)m_\beta(\nu'_k)
\]

with

\[
\frac{d}{de}m_\beta(\nu'_k + e\rho) = \frac{d}{de} \int_{S_k} e^{\beta(e_\omega, M_\beta(\nu'_k + e\rho))} \alpha(d\tilde{\omega})
\]

\[
= \beta(\frac{d}{de} \int_{S_k} e^{\beta(e_\omega, M_\beta(\nu'_k))} (e_\omega, \frac{d}{de}M_\beta(\nu' + e\rho)) \alpha(d\tilde{\omega}) \int_{S_k} e^{\beta(e_\omega, M_\beta(\nu'_k))} (e_\omega, \frac{d}{de}M_\beta(\nu' + e\rho)) \alpha(d\tilde{\omega}))
\]

\[
= \frac{d}{de}M_\beta(\nu'(k)) W(k, M_\beta(\nu')) = \frac{d}{de}M_\beta(\nu' + e\rho).
\]
Synchronization for discrete mean-field rotators

Recall \( e_\omega = \begin{pmatrix} \cos(\omega) \\ \sin(\omega) \end{pmatrix} \) then \( W(k, M_\beta(\nu')) = \beta \begin{pmatrix} A(k) & B(k) \\ B(k) & C(k) \end{pmatrix} \) is a \( 2 \times 2 \) matrix with

\[
A(k) := \frac{\int_{S_k} \cos(\omega) e^{\beta(\omega \cdot M_\beta(\nu'))} \alpha(d\omega)}{\int_{S_k} e^{\beta(\omega \cdot M_\beta(\nu'))} \alpha(d\omega)} - \left( \frac{\int_{S_k} \cos(\omega) e^{\beta(\omega \cdot M_\beta(\nu'))} \alpha(d\omega)}{\int_{S_k} e^{\beta(\omega \cdot M_\beta(\nu'))} \alpha(d\omega)} \right)^2
\]

\[
B(k) := \frac{\int_{S_k} \cos(\omega) \sin(\omega) e^{\beta(\omega \cdot M_\beta(\nu'))} \alpha(d\omega)}{\int_{S_k} e^{\beta(\omega \cdot M_\beta(\nu'))} \alpha(d\omega)} - \frac{\int_{S_k} \cos(\omega) e^{\beta(\omega \cdot M_\beta(\nu'))} \alpha(d\omega) \cdot \int_{S_k} \sin(\omega) e^{\beta(\omega \cdot M_\beta(\nu'))} \alpha(d\omega)}{\left( \int_{S_k} e^{\beta(\omega \cdot M_\beta(\nu'))} \alpha(d\omega) \right)^2}
\]

\[
C(k) := \frac{\int_{S_k} \sin^2(\omega) e^{\beta(\omega \cdot M_\beta(\nu'))} \alpha(d\omega)}{\int_{S_k} e^{\beta(\omega \cdot M_\beta(\nu'))} \alpha(d\omega)} - \left( \frac{\int_{S_k} \sin(\omega) e^{\beta(\omega \cdot M_\beta(\nu'))} \alpha(d\omega)}{\int_{S_k} e^{\beta(\omega \cdot M_\beta(\nu'))} \alpha(d\omega)} \right)^2
\]

some functions of the covariances. Consequently

\[
\frac{d}{dx} M_\beta(\nu' + \varepsilon \rho) = \sum_l \rho(l)[I_{2 \times 2} - \sum_k \nu'(k) W(k, M_\beta(\nu'))]^{-1} m_\beta(\nu') \quad (3.4)
\]

whenever the inverse matrix exists.

Up to this point all calculations are made for general \( \nu' \in \mathcal{P}\{1, \ldots, q\} \). But we are only interested in stability results at the equidistribution \( (eq) \). For \( \nu' = eq \) the inverse matrix exists as will become clear from the following calculations.

\[
dF_{eq}(\rho)(k) = \frac{1}{q} \left[ \frac{d}{dx} e(k - 1, eq + \varepsilon \rho) - \frac{d}{dx} e(k, eq + \varepsilon \rho) \right] + \frac{q}{2\pi} \left( \rho(k - 1) - \rho(k) \right).
\]

Since \( m_\beta(eq) = \frac{q}{2\pi} \int_{S_k} e_\omega \alpha(d\omega) \) we can write

\[
\frac{d}{dx} e(k, eq + \varepsilon \rho) = \frac{\beta q}{2\pi} \left[ (eq + q) \frac{d}{dx} M_\beta(eq + \varepsilon \rho) - q \int_{S_k} e_\omega \alpha(d\omega), \frac{d}{dx} M_\beta(eq + \varepsilon \rho) \right]
\]

\[
= \frac{\beta q}{2\pi} \left( \cos(\frac{2\pi}{q} q) - \frac{q}{2\pi} \int_{S_k} e_\omega \alpha(d\omega), \sin(\frac{2\pi}{q} k) - \frac{q}{2\pi} \int_{S_k} e_\omega \alpha(d\omega) \right) \frac{d}{dx} M_\beta(eq + \varepsilon \rho).
\]

Using the vector

\[
v(k) = \begin{pmatrix} \frac{q}{2\pi} \left( \int_{S_k} \cos(\omega) \alpha(d\omega) - \int_{S_{k-1}} \cos(\omega) \alpha(d\omega) \right) + \int_{S_k} \sin(\omega) \alpha(d\omega) \\ \frac{q}{2\pi} \left( \int_{S_k} \sin(\omega) \alpha(d\omega) - \int_{S_{k-1}} \sin(\omega) \alpha(d\omega) \right) - \int_{S_k} \cos(\omega) \alpha(d\omega) \end{pmatrix}
\]

which is close to zero for large \( q \), we can write

\[
dF_{eq}(\rho)(k) = \frac{q}{2\pi} \left( \rho(k - 1) - \rho(k) \right) + \frac{\beta}{2\pi} \left( v(k), \frac{d}{dx} M_\beta(eq + \varepsilon \rho) \right).
\]

Before we go on with the analysis of \( \frac{d}{dx} M_\beta(eq + \varepsilon \rho) \) let us remark:

**Remark 3.2.** For small \( \beta \), \( dF_{eq} \) is a small perturbation of the rotation matrix \( \frac{q}{2\pi}(D - I) \) with \( D_{kl} = 1_{l=k+1} \). Thinking of \( \frac{q}{2\pi} \) as a time rescaling, one can consider the linear system of differential equations on probability vectors \( x \) of length \( q \)

\[
\dot{x} = (D - I)x.
\]

Using discrete Fourier transform, it is immediately seen, that this system is attractive towards the equidistribution.
Synchronization for discrete mean-field rotators

Let us look at the effect of the perturbation:

\[
\frac{d}{d\varepsilon} M_\beta(eq + \varepsilon \rho) = \sum_l \rho(l) [I_{2 \times 2} - \frac{1}{q} \sum_k W(k, 0)]^{-1} m_\beta(\nu_k^q)
\]

where \( I_{2 \times 2} - \frac{1}{q} \sum_k W(k, 0) = \begin{pmatrix} 1 - \frac{q}{2} (1 - (\frac{q}{2})^2 \sin^2(\frac{\pi}{q})) & 0 \\ 0 & 1 - \frac{q}{2} (1 - (\frac{q}{2})^2 \sin^2(\frac{\pi}{q})) \end{pmatrix} \). This matrix is invertible as long as \( \beta(1 - (\frac{q}{2})^2 \sin^2(\frac{\pi}{q})) \neq 2 \). By the arguments provided in the second part of the proof of Theorem 1.9 below, \( \beta(1 - (\frac{q}{2})^2 \sin^2(\frac{\pi}{q})) < 2 \) in the relevant parameter regimes. Hence we can write

\[
\frac{d}{d\varepsilon} M_\beta(eq + \varepsilon \rho) = \frac{q}{2\pi - \beta\pi(1 - (\frac{q}{2})^2 \sin^2(\frac{\pi}{q}))} \sum_l \rho(l) \int_{S_l} e_\omega \alpha(d\omega)
\]

and thus

\[
dF_{eq}(\rho)(k) = \frac{q}{2\pi} (q(\rho(k) - 1) - \rho(k)) \\
+ \frac{\beta}{2\pi - \beta\pi(1 - (\frac{q}{2})^2 \sin^2(\frac{\pi}{q}))} \sum_l \left( \int_{S_l} e_\omega \alpha(d\omega), v(l) \rho(l) \right) \\
= \frac{q}{2\pi} (q(\rho(k) - 1) - \rho(k)) + \frac{4\beta \sin^2(\frac{\pi}{q})}{2\pi - \beta\pi(1 - (\frac{q}{2})^2 \sin^2(\frac{\pi}{q}))} \sum_l \sin\frac{2\pi}{q}(k - l)\rho(l) \\
+ \frac{2\beta q \sin^2(\frac{\pi}{q})}{2\pi^2 - \beta\pi^2(1 - (\frac{q}{2})^2 \sin^2(\frac{\pi}{q}))} \sum_l \left( \cos\frac{2\pi}{q}(k - l) - \cos\frac{2\pi}{q}(k - l - 1) \right) \rho(l).\]

In matrix notation this is

\[
\tilde{M}_\beta(i, j) := \frac{q}{2\pi} \left( \delta_{j,i-1} - \delta_{j,i} + c_1 \sin\frac{2\pi}{q}(i - j) \\
+ c_2 \cos\frac{2\pi}{q}(i - j) - \cos\frac{2\pi}{q}(i - j - 1) \right)
\]

where the property \( \sum_j \tilde{M}_\beta(i, j) = 0 \) for all \( i \in \{1, \ldots, q\} \) reflects conservation of mass.

**Lemma 3.3.** The eigenvalues of \( \tilde{M} \) are given by

\[
\lambda_1 = \frac{q}{2\pi} \left( (c_2 q - 2) (1 - \cos\frac{2\pi}{q}) \right) + i[(c_2 q - 1) \sin\frac{2\pi}{q} - c_1 \frac{q}{2}] \\
\lambda_j = \frac{q}{2\pi} \left( (\cos\frac{2\pi}{q} q - j) + i \sin\frac{2\pi}{q} j \right) \quad \text{for } j \in \{2, \ldots, q - 2\} \\
\lambda_{q-1} = \frac{q}{2\pi} \left( (c_2 q - 2) (1 - \cos\frac{2\pi}{q}) \right) - i[(c_2 q - 1) \sin\frac{2\pi}{q} - c_1 \frac{q}{2}] \\
\lambda_q = 0.
\]

where \( c_1 = \frac{4\beta \pi \sin^2(\frac{\pi}{q})}{2\pi^2 - \beta\pi^2 + \beta q \sin^2(\frac{\pi}{q})} \) and \( c_2 = \frac{2\beta q \sin^2(\frac{\pi}{q})}{2\pi^2 - \beta\pi^2 + \beta q \sin^2(\frac{\pi}{q})} \).

**Proof of Lemma 3.3:** Since \( \tilde{M} \) is rotation invariant, we can employ discrete Fourier transformation to calculate the eigenvalues and eigenvectors of \( \tilde{M} \). The \( k \)-th eigenvector is given by

\[
u_k = \frac{1}{\sqrt{q}} \exp(i \frac{2\pi}{q} k l)_{l \in \{1, \ldots, q\}}
\]
Synchronization for discrete mean-field rotators

and with \( \tilde{M}_\beta(n) := \tilde{M}(i, (i + n) \text{mod}(q)) \) the \( k \)-th eigenvalue reads

\[
\lambda_k = \sum_{n=0}^{q-1} \tilde{M}_\beta(n) \exp(-i \frac{2\pi}{q} kn).
\]

Calculating separately for the summands in \( \tilde{M} \), the result follows.

Notice, the eigenvalues always come in conjugated pairs. The eigenvectors have zero weight (except for the one belonging to the zero eigenvalue).

\[ \text{Figure 3: Spectrum of } \tilde{M} \text{ for } q = 100, \beta = 50. \text{ The two positive real-part eigenvalues are clearly visible.} \]

**Proof of Theorem 1.9:** The eigenspaces for the eigenvalues \( \lambda_2, \ldots, \lambda_{q-2} \) have negative real part and therefore belong to the attractive manifold of the equidistribution. The eigenspaces for the perturbated eigenvalues \( \lambda_1, \lambda_{q-1} \) form a locally non-attractive manifold if

\[
\frac{2\pi}{q} \text{Re}(\lambda_{1,q-1}) = (\cos(\frac{2\pi}{q}) - 1)(1 - \frac{q^2 c_2}{2}) > 0
\]

or equivalently if \( \frac{q^2 c_2}{2} = \frac{\beta q^2 \sin^2(\frac{\pi}{q})}{2\pi^2 - \beta^2 \pi^2 \sin^2(\frac{\pi}{q})} > 1 \). Since we assume \( \beta > 2 \) this is again equivalent to \( 2 > \beta(1 - \frac{q^2}{2} \sin^2(\frac{\pi}{q})) \). Now if \( 2 > \beta(1 - \frac{q^2}{2} \sin^2(\frac{\pi}{q})) \) (in other words (2.11) fails and we are in parameter regimes where our construction is not excluded from being welldefined), then \( 2 > \beta(1 - \frac{q^2}{2} \sin^2(\frac{\pi}{q})) \). But this is true since \( \beta(1 - \frac{q^2}{2} \sin^2(\frac{\pi}{q})) > \beta(1 - \frac{q^2}{2} \sin^2(\frac{\pi}{q})) \) is equivalent to \( \cos(\frac{\pi}{q}) < \frac{q}{2} \sin(\frac{\pi}{q}) \) and \( \frac{q}{2} \sin(\frac{\pi}{q}) = \cos(\xi) \) for some \( \xi \in [0, \frac{\pi}{q}] \). Thus in the relevant parameter regimes there exists a non-attractive manifold given by the lowest Fourier modes.

An illustration is given in Figure 1. Notice, \( \lim_{q \to \infty} \frac{q^2 c_2}{2} = \frac{\beta}{2} \) and hence all real parts go to zero as they should. We would like to point out, that in [27] although a rotation dynamics on the continuous system driven by Brownian motion is considered, similar attractivity conditions appear. In particular, in the low temperature regime, the periodic orbit attracts every measure, except the equidistribution and whatever is attracted to it. The attractive manifold for the equidistribution is also given by a continuous version of our attractive manifold given by

\[
\{ \nu' \in \mathcal{P}([1, \ldots, q]) | \sum_{k=1}^{q} \nu'(k) \exp(i \frac{2\pi}{q} k) = 0 \text{ and } \sum_{k=1}^{q} \nu'(k) \exp(-i \frac{2\pi}{q} k) = 0 \}.
\]
