Symplectic structures from Lefschetz pencils in high dimensions

ROBERT E GOMPF

Abstract  A symplectic structure is canonically constructed on any manifold endowed with a topological linear $k$–system whose fibers carry suitable symplectic data. As a consequence, the classification theory for Lefschetz pencils in the context of symplectic topology is analogous to the corresponding theory arising in differential topology.

AMS Classification  57R17

Keywords  Linear system, vanishing cycle, monodromy

1 Introduction

There is a classical dichotomy between flexible, topological objects such as smooth manifolds, and rigid, geometric objects such as complex algebraic varieties. Symplectic manifolds lie somewhere between these two extremes, raising the question of whether they should be considered as fundamentally topological or geometric. One approach to this question can be traced back to Lefschetz, who attempted to bridge the gap between topology and algebraic geometry by introducing topological (fibrationlike) structures now called Lefschetz pencils on any algebraic variety. These structures and more general linear systems can also be defined in the setting of differential topology, where they can be found on many manifolds that do not admit algebraic structures, and provide deep information about the topology of the underlying manifolds. It is now becoming apparent that the appropriate context for studying linear systems is not algebraic geometry, but a larger context that includes all symplectic manifolds. Every closed symplectic manifold (up to deformation) admits linear 1–systems (Lefschetz pencils) [4] and 2–systems [3], and it seems reasonable to expect linear $k$–systems for all $k$. Conversely, linear $(n − 1)$–systems on smooth $2n$–manifolds determine symplectic structures [5]. In this paper, we show that for any $k$, a linear $k$–system, endowed with suitable symplectic data on the

Published 20 September 2004: © Geometry & Topology Publications
fibers, determines a symplectic structure on the underlying manifold (Theorem 2.3). We then apply this to the study of Lefschetz pencils, to provide a framework in which symplectic structures appear much more topological than algebrogometric. While Lefschetz pencils in the algebrogometric world carry delicate algebraic structure, topological Lefschetz pencils have a classification theory expressed entirely in terms of embedded spheres and a diffeomorphism group of the fiber. The main conclusion of this article (Theorem 3.3) is that symplectic Lefschetz pencils have an analogous classification theory in terms of Lagrangian spheres and a symplectomorphism group of the fiber. That is, the subtleties of symplectic geometry do not interfere with a topological approach to classification.

To construct a prototypical linear $k$–system on a smooth algebraic variety $X \subset \mathbb{CP}^N$ of complex dimension $n$, simply choose a linear subspace $A \subset \mathbb{CP}^N$ of codimension $k + 1$, with $A$ transverse to $X$. The base locus $B = X \cap A$ is a complex submanifold of $X$ with codimension $k + 1$. The subspace $A \subset \mathbb{CP}^N$ lifts to a codimension–$(k + 1)$ linear subspace $\tilde{A} \subset \mathbb{C}^{N+1}$, and projection to $\mathbb{C}^{N+1}/\tilde{A} \cong \mathbb{C}^{k+1}$ descends to a holomorphic map $\mathbb{CP}^N - A \to \mathbb{CP}^k$ whose restriction will be denoted $f : X - B \to \mathbb{CP}^k$. The fibers $F_y = f^{-1}(y) \cup B$ of this linear $k$–system are the intersections of $X$ with the codimension–$k$ linear subspaces of $\mathbb{CP}^N$ containing $A$. The transversality hypothesis guarantees that $B \subset X$ has a tubular neighborhood $V$ with a complex vector bundle structure $V \rightarrow B$ such that $f$ restricts to projectivization $\mathbb{C}^{k+1} - \{0\} \to \mathbb{CP}^k$ (up to action by $GL(k+1, \mathbb{C})$) on each fiber.

To generalize this structure to a smooth $2n$–manifold $X$, we first need to relax the holomorphicity conditions. Recall that an almost-complex structure $J : TX \to TX$ on $X$ is a complex vector bundle structure on the tangent bundle (with each $J_x : T_xX \to T_xX$ representing multiplication by $i$). This is much weaker than a holomorphic structure on $X$. For our purposes, it is sufficient to assume $J$ is continuous (rather than smooth). We impose such a structure on $X$, but rather than requiring $f : X - B \to \mathbb{CP}^k$ to be $J$–holomorphic (complex linear on each tangent space), it suffices to impose a weaker condition. Let $\omega_{\text{std}}$ denote the standard (Kähler) symplectic structure on $\mathbb{CP}^k$, normalized so that $\int_{\mathbb{CP}^k} \omega_{\text{std}} = 1$. (Recall that a symplectic structure is a closed 2–form that is nondegenerate as a bilinear form on each tangent space.) We require $J$ on $X$ to be $(\omega_{\text{std}}, f)$–tame in the following sense:

**Definition 1.1** [5] For a $C^1$ map $f : X \to Y$ and a 2–form $\omega$ on $Y$, an almost-complex structure $J$ on $X$ is $(\omega, f)$–tame if $f^*\omega(v, Jv) > 0$ for all $v \in TX - \ker df$.

*Geometry & Topology Monographs, Volume 7 (2004)*
In the special case $f = \text{id}_X$, this reduces to the standard notion of $J$ being $\omega$-tame. In that case, imposing the additional condition that $\omega(Jv, Jw) = \omega(v, w)$ for all $x \in X$ and $v, w \in T_xX$ gives the notion of $\omega$-compatibility. For example, the standard complex structure on $\mathbb{CP}^k$ is $\omega_{\text{std}}$-compatible, so the standard complex structure on our algebraic prototype $X \subset \mathbb{CP}^N$ is $(\omega_{\text{std}}, f)$-tame for $f: X - B \to \mathbb{CP}^k$ as above. For $f = \text{id}_X$, the $\omega$-tameness condition (unlike $\omega$-compatibility) is open, i.e., preserved under small perturbations of $\omega$ and $J$, and a closed $\omega$ taming some $J$ is automatically symplectic (since it is nondegenerate: every nonzero $v \in TX$ pairs nontrivially with something, namely $Jv$). Such pairs $\omega$ and $J$ determine the same orientation on $X$. In general, the $(\omega, f)$-tameness condition is preserved under taking convex combinations of forms $\omega$ (for fixed $J, f$). If $J$ is $(\omega, f)$-tame, then each ker $df_x \subset T_xX$ is a $J$-complex subspace (characterized as those $v \in T_xX$ for which $f^*\omega(v, Jv) = 0$), so away from critical points each $f^{-1}(y)$ is a $J$-complex submanifold of $X$.

We can now define linear systems on smooth manifolds:

**Definition 1.2** For $k \geq 1$, a linear $k$-system $(f, J)$ on a smooth, closed $2n$-manifold $X$ is a closed, codimension-$2(k + 1)$ submanifold $B \subset X$, a smooth $f: X - B \to \mathbb{CP}^k$, and a continuous almost-complex structure $J$ on $X$ with $J|X - B$ $(\omega_{\text{std}}, f)$-tame, such that $B$ admits a neighborhood $V$ with a (smooth, correctly oriented) complex vector bundle structure $\pi: V \to B$ for which $f$ is projectivization on each fiber.

For each $y \in \mathbb{CP}^k$, the fiber $F_y = f^{-1}(y) \cup B$ is a closed subset of $X$ whose intersection with $V$ is a smooth, codimension-$2k$ submanifold. $F_y$ is a $J$-holomorphic submanifold away from the critical points of $f$, since $J$ is $(\omega_{\text{std}}, f)$-tame on $X - B$ and continuous at $B$. The complex orientation of $F_y$ agrees with the preimage orientation induced from the complex orientations of $X$ and $\mathbb{CP}^k$. The base locus $B = F_y \cap F_{y'}$ ($y' \neq y \in \mathbb{CP}^k$) is $J$-holomorphic. The complex orientation of $B$, which in the transverse case $k = 1$ is also the intersection orientation of $F_y \cap F_{y'}$, determines the “correct” orientation for the fibers of $\pi$. Later (Lemma 2.1) we will verify that the complex bundle structure on $V$ can be assumed to come from $J$ on $TX|B$ by the Tubular Neighborhood Theorem.

Our first goal is to construct symplectic structures using linear $k$-systems. This was already achieved in [5] for hyperpencils, which are linear $(n - 1)$-systems endowed with some additional structure taken from the algebraic prototype. It was shown that every hyperpencil determines a unique symplectic form up to isotopy. (Symplectic forms $\omega_0$ and $\omega_1$ on $X$ are isotopic if there is a diffeomorphism $\psi: X \to X$ isotopic to $\text{id}_X$ with $\psi^*\omega_0 = \omega_1$.) The proof crucially used
the fact that fibers of linear \((n - 1)\)-systems are oriented surfaces (away from the critical points) — note that by Moser’s Theorem [9] every closed, connected, oriented surface admits a unique symplectic form (i.e. area form) up to isotopy and scale. For \(k < n - 1\), the fibers will have higher dimension, so symplectic forms on them need neither exist nor be unique, and we must hypothesize existence and some compatibility of symplectic structures on the fibers. Similarly, almost-complex structures exist essentially uniquely on oriented surfaces, so the required almost-complex structure on a hyperpencil can be essentially uniquely constructed, given only a local existence hypothesis at the critical points. For higher dimensional fibers, there seems to be no analogous procedure, requiring us to include a global almost-complex structure in the defining data of a linear \(k\)-system. (Consider the projection \(S^2 \times S^4 \to S^2\) which can be made holomorphic locally, but whose fibers admit no almost-complex structure.) The main result for constructing symplectic forms on linear \(k\)-systems is Theorem 2.3. The statement is rather technical, but can be informally summed up as follows:

**Principle 1.3** For a linear \(k\)-system \((f, J)\) on \(X\), suppose that the fibers admit \(J\)-taming symplectic structures (suitably interpreted at the critical points), and that these can be chosen to fit together suitably along \(B\) and in cohomology. Then \((f, J)\) determines an isotopy class of symplectic forms on \(X\).

The isotopy class of forms can be explicitly characterized (Addenda 2.4 and 2.6).

Our main application concerns Lefschetz pencils on smooth manifolds. These are structures obtained by generalizing the generic algebraic prototype of linear 1-systems.

**Definition 1.4** A **Lefschetz pencil** on a smooth, closed, oriented \(2n\)-manifold \(X\) is a closed, codimension-4 submanifold \(B \subset X\) and a smooth \(f: X - B \to \mathbb{CP}^1\) such that

1. \(B\) admits a neighborhood \(V\) with a (smooth, correctly oriented) complex vector bundle structure \(\pi: V \to B\) for which \(f\) is projectivization on each fiber,

2. for each critical point \(x\) of \(f\), there are orientation-preserving coordinate charts about \(x\) and \(f(x)\) (into \(\mathbb{C}^n\) and \(\mathbb{C}\), respectively) in which \(f\) is given by \(f(z_1, \ldots, z_n) = \sum_{i=1}^{n} z_i^2\), and

3. \(f\) is 1–1 on the critical set \(K \subset X\).
Condition (2) implies $K$ is finite, so (3) can always be achieved by a perturbation of $f$. A Lefschetz pencil, together with an $(\omega_{\text{std}}, f)$–tame almost-complex structure $J$, is a linear 1–system (although the latter can have more complicated critical points). Such a Lefschetz 1–system can be constructed as before on any smooth algebraic variety by using a suitably generic linear subspace $A \cong \mathbb{C}P^{N-2} \subset \mathbb{C}P^N$. On the other hand, projection $S^2 \times S^4 \to S^2 = \mathbb{C}P^1$ gives a (trivial) Lefschetz pencil admitting no such $J$.

The topology of Lefschetz pencils is understood at the most basic level, e.g. [8] or (in dimension 4) [7]. We first consider the case with $B = \emptyset$, or Lefschetz fibrations $f : X^{2n} \to S^2$. Choose a collection $A = \bigcup A_j \subset S^2$ of embedded arcs with disjoint interiors, connecting the critical values to a fixed regular value $y_0 \in S^2$. Over a sufficiently small disk $D \subset S^2$ containing $y_0$, we see the trivial bundle $D \times F_{y_0} \to D$. Expanding $D$ to include an arc $A_j$ adds an $n$–handle along an $(n-1)$–sphere lying in a fiber. Thus, if we expand $D$ to include $A$, the result is specified by a cyclically ordered collection of vanishing cycles, i.e. embeddings $S^{n-1} \to F_{y_0}$ with suitable normal data. However, this ordered collection depends on our choice of $A$. Any change in $A$ can be realized by a sequence of Hurwitz moves, moving some arc $A_j$ past its neighbor $A_{j \pm 1}$.

The effect of a Hurwitz move on the ordered collection of vanishing cycles can be easily described using the monodromy of the fibration around $A_{j \pm 1}$, which is an explicitly understood element of $\pi_0$ of the diffeomorphism group $\mathcal{D}$ of $F_{y_0}$. (See Section 3.) Over the remaining disk $S^2 - \text{int } D$, we again have a trivial bundle, so the product of the monodromies of the vanishing cycles must be trivial, and then the Lefschetz fibrations extending fixed data over $D$ are classified by $\pi_1(\mathcal{D})$. The correspondence with $\pi_1(\mathcal{D})$ is determined by fixing an arc from $y_0$ to $\partial D$ (avoiding $A$) and a trivialization of $f$ over $\partial D$. Hurwitz moves involving the new arc will induce additional equivalences. For the case $B \neq \emptyset$, we blow up $B$ to obtain a Lefschetz fibration, then apply the previous analysis. However, extra care is required to preserve the blown up base locus and its normal bundle. We must take $\mathcal{D}$ to be the group of diffeomorphisms of $F$ fixing $B$ and its normal bundle, and the product of monodromies will now be a nontrivial normal twist $\delta$ around $B$. We state the result carefully as Proposition 3.1. For now, we sum up the discussion as follows:

**Principle 1.5** To classify Lefschetz pencils with a fixed fiber and base locus, first classify, up to Hurwitz moves, cyclically ordered collections of vanishing cycles for which the product of monodromies is $\delta \in \pi_0(\mathcal{D})$. For any fixed choice of arcs and vanishing cycles, the resulting Lefschetz pencils are classified by $\pi_1(\mathcal{D})$. The final classification results from modding out the effects of Hurwitz moves.
on the last fiber. (One may also choose to mod out by self-diffeomorphisms of the fiber \((F_{y_0}, B)\).)

Of course, this is an extremely difficult problem in general, but at least we know where to start.

If \(X\) is given a symplectic structure \(\omega\) that is symplectic on the fibers, then the above description can be refined. The vanishing cycles will be Lagrangian spheres (ie \(\omega\) restricts to 0 on them), and the monodromies will be symplectomorphisms (diffeomorphisms preserving \(\omega\)) [2, 10, 11]. The discussion of arcs and Hurwitz moves proceeds as before, where \(D\) is replaced by a suitable group \(D_{\omega_f}\) of symplectomorphisms of the fiber. However, symplectic forms are a priori global analytic objects (satisfying the partial differential equation \(d\omega = 0\)), so for symplectic forms on \(X\) compatible with a given Lefschetz pencil, one might expect both the existence and uniqueness questions to involve delicate analytic invariants. Our main result (Theorem 3.3) is that no such difficulties arise, provided that we choose our definitions with suitable care, for example requiring \([\omega] \in H^2_{\text{DR}}(X)\) to be Poincaré dual to the fibers (as is the case for Donaldson’s pencils [4]). We obtain:

**Principle 1.6** The classification of (suitably defined) symplectic Lefschetz pencils is purely topological, ie analogous to that of Principle 1.5. More precisely, for a suitable symplectic manifold pair \((F, B)\), let \(i_*\) denote the \(\pi_1\)-homomorphism induced by inclusion \(\mathcal{D}_{\omega_f} \subset \mathcal{D}\). Then for fixed (suitably symplectic) data over \(D\) as preceding Principle 1.5, a given Lefschetz pencil admits a suitably compatible symplectic structure if and only if it is classified by an element of \(\text{Im} i_*\). Then such structures are classified up to suitable isotopy by \(\pi_2(\mathcal{D}/\mathcal{D}_{\omega_f})\), and by \(\ker i_*\) if symplectomorphisms preserving \(f\) and fixing \(f^{-1}(D)\) are also allowed.

This is the same sort of topological classification one obtains for extending bundle structures over a 2–cell: Given groups \(H \subset G\), a space \(Y \cup \partial Y\)–cell, and a fixed \(H\)–bundle over \(Y\) (on which we do not allow automorphisms), \(G\)–bundle and \(H\)–bundle extensions (if they exist) are classified by \(\pi_1(G) \cong \pi_2(BG)\) and \(\pi_1(H) \cong \pi_2(BH)\), respectively. Inclusion \(i: H \to G\) induces an exact sequence

\[\pi_2(G/H) \xrightarrow{\partial_*} \pi_1(H) \xrightarrow{i_*} \pi_1(G)\]

with \(i_*\) corresponding to the forgetful map from \(H\)–structures to \(G\)–structures. Thus \(\text{Im} i_*\) classifies \(G\)–extensions admitting \(H\)–reductions, and \(\ker i_* = \text{Im} \partial_*\) classifies \(H\)–reductions of a fixed \(G\)–extension as abstract \(H\)–extensions. However, different \(H\)–reductions can be abstractly \(H\)–isomorphic via a \(G\)–bundle

*Geometry & Topology Monographs, Volume 7 (2004)*
automorphism supported over the 2–cell, and if we disallow such equivalences, $H$–reductions of a fixed $G$–extension are classified by $\pi_2(G/H)$.

2 Linear systems

In this section, we show how to construct symplectic structures from linear systems with suitable symplectic data along the fibers (Principle 1.3). Our construction is modeled on the corresponding method for hyperpencils [5, Theorem 2.11], but is complicated by the fact that the base locus need no longer be 0–dimensional. We must first gain more control of the normal data along $B$. Given a linear $k$–system $(f,J)$ on $X$ as in Definition 1.2, let $\nu \to B$ be any $J$–complex subbundle of $TX|B$ complementary to $TB$. (This exists since $B$ is a $J$–holomorphic submanifold of $X$.) Then the bundle structure $\pi: V \to B$ guaranteed on a neighborhood of $B$ (by Definition 1.2) can be arranged (after precomposing $\pi$ with an isotopy preserving $f$) to have its fibers tangent to $\nu$ along $B$.

Lemma 2.1 For $\nu$ and $\pi$ as above, the complex bundle structure on $\pi$ (given by Definition 1.2) restricts to $J$ on $\nu$.

Proof Near $B$, extend $TB$ to a $J$–complex subbundle $H$ of $TX$ complementary to the fibers of $\pi$ and tangent to the fibers $F_y$ of $f$. Then $J$ induces a complex structure near $B$ on $TX/H$. The latter bundle is canonically $\mathbb{R}$–isomorphic to the bundle of tangent spaces to the fibers of $\pi$; let $J'$ denote the resulting almost-complex structure on the fibers of $\pi$. Clearly, $J' = J$ on $\nu$, so it suffices to show that $J'$ agrees with the complex structure of $\pi$ on $\nu$. This follows immediately from [5, Lemma 4.4(b)], which is restated below. (Note that for $x \notin B$, $H_x$ lies in $\ker df_x$, so $J'$ is $(\omega_{\text{std}}, f)$–tame at $x$ since $J$ is.)

Lemma 2.2 [5] If $f: \mathbb{C}^n - \{0\} \to \mathbb{CP}^{n-1}$ denotes projectivization, $n \geq 2$, and $J$ is a continuous (positively oriented) almost-complex structure on a neighborhood $W$ of 0 in $\mathbb{C}^n$, with $J|W - \{0\}$ $(\omega_{\text{std}}, f)$–tame, then $J|T_0\mathbb{C}^n$ is the standard complex structure.

The main idea of the proof is that $J|T_0\mathbb{C}^n$ has the same complex lines as the standard structure (since the complex lines of $\mathbb{C}^n$ are $J$–complex by $(\omega_{\text{std}}, f)$–tameness), and a linear complex structure is determined by its complex lines.

We can now state the main theorem of this section. By Lemma 2.1, the canonical identification of the vector bundle $\pi: V \to B$ with the normal bundle $\nu$
of its 0–section is a $J$–complex isomorphism. This complex bundle is projectively trivialized by $f$ (in Definition 1.2), so we can reduce the structure group of $\nu$ to $U(1)$ (acting diagonally on $\mathbb{C}^{k+1}$) by choosing a suitable Hermitian structure on $\nu$. This Hermitian structure is canonically determined up to a positive scalar function. Let $h$ denote the hyperplane class in $H^{2}_{\text{dR}}(\mathbb{CP}^{k})$ dual to $[\mathbb{CP}^{k-1}]$, and let $c_{f} \in H^{2}_{\text{dR}}(X)$ correspond to $f^{*}h \in H^{2}_{\text{dR}}(X - B)$ under the obvious isomorphism. (Recall codim $B \geq 4$.)

**Theorem 2.3** Let $(f, J)$ be a linear $k$–system on $X$. Choose a $J$–complex subbundle $\nu \subset TX|B$ complementary to $TB$, and a Hermitian form on $\nu$ as above. Suppose there is a symplectic form $\omega_{B}$ on $B$ taming $J|B$, with $[\omega_{B}] = c_{f}|B \in H^{2}_{\text{dR}}(B)$. Then $\omega_{B}$ extends to a closed 2–form $\zeta$ on $X$ representing $c_{f}$, with $\nu$ and $TB$ $\zeta$–orthogonal, and $\zeta$ agreeing with the given Hermitian form on each 1–dimensional $J$–complex subspace of $\nu$. Given such an extension $\zeta$, suppose that each $F_{y}$, $y \in \mathbb{CP}^{k}$, has a neighborhood $W_{y}$ in $X$ with a closed 2–form $\eta_{y}$ on $W_{y}$ taming $J|\ker df_{x}$ for all $x \in W_{y} - B$, agreeing with $\zeta$ on each $TF_{z}|B$, $z \in \mathbb{CP}^{k}$, and with $[\eta_{y} - \zeta] = 0 \in H^{2}_{\text{dR}}(W_{y}, B)$. Then $(f, J)$ determines an isotopy class $\Omega$ of symplectic forms on $X$ representing $c_{f} \in H^{2}_{\text{dR}}(X)$.

Each $\ker df_{x}$ is $J$–complex, so we define $\eta_{y}$–tameness on it in the obvious way. The class $[\eta_{y} - \zeta] \in H^{2}_{\text{dR}}(W_{y}, B)$ is defined since $\eta_{y} - \zeta$ vanishes on $B$ by hypothesis. This class vanishes automatically if $[\eta_{y}] = c_{f}|W_{y}$ and the restriction map $H^{1}_{\text{dR}}(W_{y}) \to H^{1}_{\text{dR}}(B)$ is surjective; however surjectivity always fails when (for example) $B$ is a surface of nonzero genus and a generic (4–dimensional) fiber has $b_{1} < 2$.

For our subsequent application to Lefschetz pencils, we will need an explicit characterization of $\Omega$ and detailed properties of some of its representatives. The characterization below is complicated by our need to perturb $J$ during the proof. A simpler version when no perturbation is necessary will be given as Addendum 2.6 after the required notation is established.

**Addendum 2.4** Fix a metric on $X$ and $\varepsilon > 0$. Let $\mathcal{J}_{\varepsilon}$ be the $C^{0}$–space of continuous almost–complex structures $J'$ on $X$ that are $\varepsilon$–close to $J$, agree with $J$ on $TX|B$ and outside the $\varepsilon$–neighborhood $U$ of $B$, and make each $F_{y} \cap U$ $J'$–complex. Fix a regular value $y_{0}$ of $f$. Then $\Omega$ contains a form $\omega$ taming an element of $\mathcal{J}_{\varepsilon}$ and extending $\omega_{B}$, such that $J$ is $\omega$–compatible on $\nu$, which is $\omega$–orthogonal to $B$, and $\omega|F_{y_{0}}$ is isotopic to $\eta|F_{y_{0}}$ by an isotopy $\psi_{s}$ of the pair $(F_{y_{0}}, B)$ that is symplectic on $(B, \omega_{B})$. For $\varepsilon$ sufficiently small, any two forms representing $c_{f}$ and tamely elements of $\mathcal{J}_{\varepsilon}$ are isotopic, so these latter conditions uniquely determine $\Omega$.
Theorem 2.3 was designed for compatibility with [5, Theorem 3.1], which was the main tool for putting symplectic structures on hyperpencils (and domains of locally holomorphic maps [6]). The proof is based on an idea of Thurston [12]. We state and prove a version of the theorem which has been slightly modified, primarily to correct for the failure of $H^1$-surjectivity observed following Theorem 2.3. We will ultimately apply the theorem to a linear system projection $f: X - B \to \mathbb{CP}^k$, working relative to a normal disk bundle $C$ of $B$ (intersected with $X - B$).

**Theorem 2.5** Let $f: X \to Y$ be a smooth map between manifolds, and let $C$ be a codimension–$0$ submanifold (with boundary) that is closed in $X$, with $X - \text{int} C$ compact. Suppose that $\omega_Y$ is a symplectic form on $Y$, and $J$ is a continuous, $(\omega_Y, f)$–tame almost-complex structure on $X$. Let $\zeta$ be a closed $2$–form on $X$ taming $J$ on $C$. Suppose that for each $y \in Y$, $f^{-1}(y) \cup C$ has a neighborhood $W_y$ in $X$, with a closed $2$–form $\eta_y$ on $W_y$ agreeing with $\zeta$ on $C$, such that $[\eta_y - \zeta] = 0 \in H^2_{\text{dR}}(W_y, C)$ and such that $\eta_y$ tames $J|\ker df_x$ for each $x \in W_y$. Then there is a closed $2$–form $\eta$ on $X$ agreeing with $\zeta$ on $C$, with $[\eta] = [\zeta] \in H^2_{\text{dR}}(X)$, and such that for all sufficiently small $t > 0$ the form $\omega_t = t\eta + f^*\omega_Y$ on $X$ tames $J$ (and hence is symplectic). For preassigned $\hat{y}_1, \ldots, \hat{y}_m \in Y$, we can assume $\eta$ agrees with $\eta_{\hat{y}_j}$ near each $f^{-1}(\hat{y}_j)$.

**Proof** For each $y \in Y$, $[\eta_y - \zeta] = 0 \in H^2_{\text{dR}}(W_y, C)$, so we can write $\eta_y = \zeta + d\alpha_y$ for some $1$–form $\alpha_y$ on $W_y$ with $\alpha_y|C = 0$. Since each $X - W_y$ is compact, each $y \in Y$ has a neighborhood disjoint from $f(X - W_y)$. Thus, we can cover $Y$ by open sets $U_i$, with each $f^{-1}(U_i)$ contained in some $W_y$, and each $\hat{y}_j$ lying in only one $U_i$. Let $\{\rho_i\}$ be a subordinate partition of unity on $Y$. The corresponding partition of unity $\{\rho_i \circ f\}$ on $X$ can be used to splice the forms $\alpha_y$; let $\eta = \zeta + d\sum_i (\rho_i \circ f)\alpha_{y_i}$. Clearly, $\eta$ is closed with $[\eta] = [\zeta] \in H^2_{\text{dR}}(X)$, $\eta = \zeta$ on $C$, and $\eta = \eta_{\hat{y}_j}$ near $f^{-1}(\hat{y}_j)$, so it suffices to show that $\omega_t$ tames $J$ ($t > 0$ small). In preparation, perform the differentiation to obtain $\eta = \zeta + \sum_i (\rho_i \circ f)d\alpha_{y_i} + \sum_i (d\rho_i \circ df) \wedge \alpha_{y_i}$. The last term vanishes when applied to a pair of vectors in $\ker df_x$, so on each $\ker df_x$ we have $\eta = \zeta + \sum_i (\rho_i \circ f)d\alpha_{y_i} = \sum_i (\rho_i \circ f)\eta_{y_i}$. By hypothesis, this is a convex combination of taming forms, so we conclude that $J|\ker df_x$ is $\eta$–tame for each $x \in X$.

It remains to show that there is a $t_0 > 0$ for which $\omega_t(v, Jv) > 0$ for every $t \in (0, t_0)$ and $v$ in the unit sphere bundle $\Sigma \subset TX$ (for any convenient metric). But

$$\omega_t(v, Jv) = t\eta(v, Jv) + f^*\omega_Y(v, Jv).$$

Since $J$ is $(\omega_Y, f)$–tame, the last term is positive for $v \notin \ker df$ and zero otherwise. Since $J|\ker df$ is $\eta$–tame, the continuous function $\eta(v, Jv)$ is positive.
for all \( v \) in some neighborhood \( U \) of \( \ker df \cap \Sigma \) in \( \Sigma \). Similarly, for \( v \in \Sigma | C \), 
\[
\eta(v, Jv) = \zeta(v, Jv) > 0.
\]
Thus, \( \omega_t(v, Jv) > 0 \) for all \( t > 0 \) when \( v \in U \cup \Sigma | C \). On the compact set \( \Sigma \setminus (X - \text{int } C) - U \) containing the rest of \( \Sigma \), \( \eta(v, Jv) \) is bounded and the last displayed term is bounded below by a positive constant, so \( \omega_t(v, Jv) > 0 \) for \( 0 < t < t_0 \) sufficiently small, as required.

**Proof of Theorem 2.3 and addenda** We begin by producing the desired symplectic structure near \( B \), via a local model generalizing the case \( \dim B = 0 \) from [5]. Assume the fibers of \( \pi \) are tangent to \( v \). Let \( L_0 \to B \) denote the Hermitian line bundle obtained by restricting \( \pi \) to a fixed \( F_y \), so \( L_0 \) and \( v \) are associated to the same principal \( U(1) \)-bundle \( \pi_P: P \to B \). Then \( \epsilon_1(L_0) = c_f | B = [\omega_B] \) (since a generic section of \( L_0 \) is obtained by perturbing \( B \cup f^{-1}(\mathbb{CP}^{k-1}) \subset X \) and intersecting it with \( F_y \)). Let \( \alpha \beta_0 \) on \( P \) be a \( U(1) \)-connection form for \( L_0 \) with Chern form \( \omega_B \), so \(-\frac{1}{2\pi} d\beta_0 = \pi_P^* \omega_B \). For \( r > 0 \), let \( S_r \subset V \) denote the sphere bundle of radius \( r \) (for the Hermitian metric). The map \((\pi, f): V - B \to B \times \mathbb{CP}^k \) exhibits each \( S_r \) as a principal \( U(1) \)-bundle. The corresponding line bundle \( L \to B \times \mathbb{CP}^k \) restricts to \( L_0 \) over \( B \) and to the tautological bundle \( L_{\text{taut}} \) over \( \mathbb{CP}^k \). Since \( H^2(\mathbb{CP}^k) \cong H^2(B) \oplus (H^0(B) \otimes H^2(\mathbb{CP}^k)) \) (over \( \mathbb{Z} \)), we conclude that \( L \cong \pi_1^* L_0 \otimes \pi_2^* L_{\text{taut}} \).

Fix this isomorphism, and let \( i \beta \) be the \( U(1) \)-connection form on \( S_r \) induced by \( \alpha \beta_0 \) on \( L_0 \) and the tautological connection on \( L_{\text{taut}} \). Then the Chern form of \( i \beta \) is given by \(-\frac{1}{2\pi} d\beta = \pi^* \omega_B - f^* \omega_{\text{std}} \) (pushed down to \( B \times \mathbb{CP}^k \)). Define a 2-form \( \omega_V \) on \( V - B \) by
\[
\omega_V = (1 - r^2) \pi^* \omega_B + r^2 f^* \omega_{\text{std}} + \frac{1}{2\pi} d(r^2) \wedge \beta.
\]
An easy calculation shows that \( d\omega_V = 0 \), and it is routine to verify [5] that \( \omega_V \) restricts to the given Hermitian form on each fiber of \( \pi \) (up to a constant factor of \( \pi \), arising from our choice of normalization of \( \omega_{\text{std}} \), which can be eliminated by a constant rescaling of \( r \)). Let \( H \) be the smooth distribution on \( V \) consisting of \( TB \) on \( B \) together with its \( \beta \)-horizontal lifts to each \( S_r \). Clearly, \( H \) is tangent to each \( S_r \) and \( F_y \), so it is \( \omega_V \)-orthogonal to the fibers of \( \pi \). Since \( \omega_V | H = (1 - r^2) \pi^* \omega_B \) extends smoothly over \( B \), as does \( \omega_V \) on the \( \pi \)-fibers, \( \omega_V \) extends smoothly to all of \( V \), with \( \omega_V | B = \omega_B \). If \( J_V \) denotes the almost-complex structure on \( V \) obtained by lifting \( J | B \) to \( H \) and summing with the complex bundle structure on the fibers of \( \pi \), then \( J_V \) is \( \omega_V \)-tame for \( r < 1 \). (Check this separately on the \( \pi \)-fibers and their \( \omega_V \)-orthogonal complements \( H \).) Note that \( J_V = J \) on \( TX | B \) (Lemma 2.1).

We can now state the remaining addendum:
Addendum 2.6 If \( J \) agrees with \( J_V \) near \( B \) for some choice of \( \pi : V \to B \)
and \( \beta_0 \) as above, then \( \Omega \) has the simpler characterization that it contains \( \omega \)-taming \( J \) with \([\omega] = c_f \). In fact, there is a \( J \)-taming form \( \omega \in \Omega \) satisfying all the conclusions of Addendum 2.4 with \( \nu \) induced by \( \pi \), and such that the given \( \psi_0^* \eta_{y_0} \) on \( F_{y_0} \) between \( \eta_{y_0} \) and \( \omega \) all tame \( J \).

To construct the required form \( \zeta \), choose a form \( \zeta_0 \) representing \( c_f \in H^2_{dR}(X) \). Then \([\omega_V - \zeta_0] = 0 \in H^2_{dR}(V) \), so there is a 1-form \( \alpha \) on \( V \) with \( d\alpha = \omega_V - \zeta_0 \). Let \( \zeta = \zeta_0 + d(\rho \alpha) \), where \( \rho : X \to \mathbb{R} \) has support in \( V \) and \( \rho = 1 \) near \( B \). Then \( \zeta = \omega_V \) near \( B \), so \( \zeta \) satisfies the required conditions for the theorem. If \( \zeta_0 \) was already the hypothesized extension of \( \omega_B \), satisfying these conditions and suitably compatible with forms \( \eta_y \), then \( \zeta_0 = \omega_V = \zeta \) on each \( TF_zB \cong TB \oplus L_0 \), so \( \zeta \) still agrees with each \( \eta_y \) as required along \( B \). We also could have arranged \( \alpha|B = 0 \) since \( H^2_{dR}(V, B) = 0 \), so that we still have \([\eta_y - \zeta] = 0 \in H^2_{dR}(W_y, B) \). Thus, we can assume the given \( \zeta \) agrees with \( \omega_V \) near \( B \).

Since we must perturb \( J \) near \( B \), we verify that for sufficiently small \( \varepsilon \), every \( J' \in \mathcal{J}_\varepsilon \) as in Addendum 2.4 is \((\omega_{std}, f)\)-tame on \( X - B \). Choose \( \varepsilon \) so that the \( \varepsilon \)-neighborhood \( U \) of \( B \) in \( X \) (in the given metric) has closure in \( V \), and let \( \Sigma \subset TX \) be the compact subset consisting of unit vectors over \( cl(U) \) that are \( \omega_V \)-orthogonal to fibers \( F_y \). For \( J' \in \mathcal{J}_\varepsilon \), each \( \ker df_x = T_x F_{f(x)} \) over \( U - B \) is \( J' \)-complex, so it suffices to show that \( f^* \omega_{std}(v, J'v) > 0 \) for \( v \in \Sigma \cap T(U - B) \).

We replace \( f^* \omega_{std} \) by \( \omega_V \), since these agree on such vectors \( v \) (which are tangent to the \( \pi \)-fibers and \( S_x \) up to the scale factor \( r^2 > 0 \). But \( \omega_V(v, J'v) > 0 \) for \( v \in \Sigma \) (since \( J \) equals \( J_V \) on \( TX | B \) and \( J = (\omega_{std}, f) \)-tame elsewhere), so the corresponding inequality holds for all \( J' \in \mathcal{J}_\varepsilon \) for \( \varepsilon \) sufficiently small, by compactness of \( \Sigma \) and openness of the taming condition.

We must also modify the pairs \((W_y, \eta_y)\) so that for all sufficiently small \( \varepsilon \), every \( J' \in \mathcal{J}_\varepsilon \) is \( \eta_y \)-tame on \( \ker df_x \) for each \( y \in \mathbb{CP}^k \) and \( x \in W_y - B \). Shrink each \( W_y \) so that \( \eta_y \) is defined on \( cl(W_y) \). Each \( W_y \) contains \( f^{-1}(U_y) \) for some neighborhood \( U_y \) of \( y \) (cf proof of Theorem 2.5). After passing to a finite subcover of \( \{U_y\} \), we can assume \( \{W_y\} \) is finite, so the pairs \((W_y, \eta_y)\) for all \( y \in \mathbb{CP}^k \) are taken from a finite set, and \( \eta_{y_0}|F_{y_0} \) is preserved. Now for each \( \eta_y, \eta_y(v, J_v) > 0 \) on the compact space of unit tangent vectors to fibers \( F_y \) in \( cl(W_y \cap V) \). (Note that on \( TX|B \), \( \zeta \) tames \( J \).) Thus, each \( J' \in \mathcal{J}_\varepsilon \) has the required \( \eta_y \)-taming for \( \varepsilon \) sufficiently small.

Next we splice our local model \( \omega_V \) and \( J_V \) into each \( \eta_y \) and \( J \). For \( y \in \mathbb{CP}^k \), \( \eta_y \) equals \( \zeta \) on \( TF_y|B \), so it tames \( J \) there and hence is symplectic on \( F_y \) near \( B \). Thus, Weinstein’s symplectic tubular neighborhood theorem

[13] on $F_y$ produces an isotopy of $F_y$ fixing $B$ (pointwise) and supported in a preassigned neighborhood of $B$, sending $\eta_y|F_y$ to a form $\eta'_y$ agreeing with $\zeta = \omega_V$ near $B$ on $F_y$. To extend $\eta'_y$ to a neighborhood of $F_y$ in $X$, first extend it as $\omega_V$ near $B$ and as $\eta_y$ farther away, leaving a gap in between (inside $V$). Let $r: W_y \to W'_y$ be a smooth map agreeing with $\text{id}_{W_y}$ away from the gap and on $F_y$, collapsing $W'_y$ onto $F_y$ near the gap. Then $r^*\eta'_y$ is a closed form near $F_y$ extending $\eta'_y$ (cf [5]). Now recall that the vector field generating Weinstein’s isotopy vanishes to second order on $B$. (It is symplectically dual to the 1–form $\int_0^1 \pi_t^*(X_t \cdot j(\eta_y - \zeta)) \, dt$, where $\pi_t$ is fiberwise multiplication by $t$, and the radial vector field $X_t = \frac{d}{dt}\pi_t$ vanishes to first order on $B$, as does $\eta_y - \zeta$.) Thus we can assume our isotopy is arbitrarily $C^1$–small (by working in a sufficiently small neighborhood of $B$), so we can replace $\eta_y$ on $W_y$ by $r^*\eta'_y$ on a sufficiently small neighborhood of $F_y$ without disturbing our original hypotheses. In particular, we can assume $J$ is still $\eta_y$–tame on each $\ker df_x$ (or similarly for all $J'$ in a preassigned compact subset of $\J_e$ with $\varepsilon$ as in the previous paragraph). Since we have shrunk the sets $W_y$, the set $\{W_y\}$ may again be infinite, but we can reduce to a finite subcollection as before. Then there is a single neighborhood $W$ of $B$ in $X$, contained in $\bigcap W_y$, on which each $\eta_y$ agrees with $\omega_V$ and $\zeta$. Since $\eta_{y_0}|F_{y_0}$ has only been changed by a $C^1$–small isotopy fixing $B$, its use in the addenda is unaffected.

To complete splicing the local model, we perturb $J$ to $J'$ agreeing with $J_V$ near $B$. Under the hypothesis of Addendum 2.6, we simply set $J' = J$. Otherwise, we invoke [5, Corollary 4.2], which was adapted from [1, page 100].

**Lemma 2.7** [5] For any finite dimensional, real vector space $V$, there is a canonical retraction $j(A) = A(-A^2)^{-1/2}$ from the open subset of operators in $\text{Aut}(V)$ without real eigenvalues to the set of linear complex structures on $V$. For any linear $T: V \to W$ with $TA = BT$, we have $Tj(A) = j(B)T$ (when both sides are defined).

Since $J = J_V$ on $TX|B$, $J_t = j((1-t)J + tJ_V)$ is well-defined for $0 \leq t \leq 1$ near $B$, and each $F_y$ is $J_t$–complex there (as seen by letting $T$ be inclusion $T_xF_y \to T_xX$). For any $\varepsilon > 0$, we can thus define $J' \in \J_{\varepsilon}$ to be $J_\rho$, for $\rho: X \to \I$ supported sufficiently close to $B$ and with $\rho \equiv 1$ near $B$, extended as $J$ away from $\text{supp} \rho$. Then for $\varepsilon$ sufficiently small, the preceding three paragraphs show that $(J, J')$ is a linear $k$–system satisfying the hypotheses of Theorem 2.3 with $J', \zeta$ and each $\eta_y$ agreeing with the standard model on a suitably reduced $W$.

We now construct a symplectic form $\omega$ on $X$ as in [5]. First we apply Theorem 2.5 to $f: X - B \to \mathbb{CP}^k$ and $J'$, with $C \subset W$ a normal disk bundle to $B$.
The form associated with taming on the blown up base locus.)

To compute the cohomology class \([\eta - \zeta] \in H^2_{dR}(W_y - B, C) \cong H^2_{dR}(W_y, B)\) vanishes as required. We obtain a closed 2–form \(\eta\) on \(X - B\) agreeing with \(\omega_V\) on \(C\) (hence extending over \(X\)), with \([\eta] = c_f \in H^2_{dR}(X)\) and \(\eta = \eta_0\) on \(F_{y_0}\), such that \(\omega_t = t\eta + f^*\omega_{\text{std}}\) tames \(J'\) on \(X - B\) for \(t > 0\) chosen sufficiently small. On \(C\), the symplectic form \(\omega_t\) is given by

\[
\omega_t(r) = t(1 - r^2)\pi^*\omega_B + (1 + tr^2)f^*\omega_{\text{std}} + \frac{t}{2\pi}d(r^2) \wedge \beta.
\]

Unfortunately, this is singular at \(B\). (Compare the middle term with that of \(\omega_V \neq 0\).) However, we can desingularize by a dilation in the manner of [5]:

The radial change of variables \(R^2 = \frac{1 + tr^2}{1 + t^2}\) shows that \(\omega_V(R) = \frac{1}{1 + t^2}\omega_t(r)\), so there is a radial symplectic embedding \(\varphi\) \((C, \frac{1}{1 + t^2}\omega_t) \to (V, \omega_V)\) onto a collar surrounding the bundle \(R^2 \leq \frac{1}{1 + t^2}\). Let \(\varphi_0 : V \to V\) be a radially symmetric diffeomorphism covering \(\text{id}_B\) and agreeing with \(\varphi\) near \(\partial C\). Let \(\omega\) be \(\varphi_0^*\omega_V\)

on \(C \cup B\) and \(\frac{1}{1 + t^2}\omega_t\) elsewhere. These pieces fit together to define a symplectic form on \(X\), since \(\varphi\) is a symplectic embedding. (This construction is equivalent to blowing up \(B\), applying Theorem 2.5 with \(C = \emptyset\) to the resulting singular fibration, and then blowing back down, but it avoids technical difficulties associated with taming on the blown up base locus.)

The form \(\omega\) satisfies the properties required by Theorem 2.3 and its addenda:

To compute the cohomology class \([\omega] \in H^2_{dR}(X)\), it suffices to work outside \(C\). Then \([\omega] = \frac{1}{1 + t^2}[\omega_t] = \frac{1}{1 + t^2}(tc_f + f^*[\omega_{\text{std}}]) = c_f\) as required, since \([\omega_{\text{std}}] = h \in H^2_{dR}(\mathbb{CP}^k)\). For Addendum 2.4, note that \(\omega\) obviously extends \(\omega_B\) and is compatible with \(J\) on \(\nu\), which is \(\omega\)-orthogonal to \(B\). Outside \(C\), we already know that \(\omega = \frac{1}{1 + t^2}\omega_t\) tames \(J' \in \mathcal{J}_t\), so taming need only be checked for \(J' = J_V\) on \(C \cup B\) with \(\omega = \varphi_0^*\omega_V\), and this is easy on \(TX|B = TB \oplus \nu\). For \(C\), consider the \(\omega_V\)-orthogonal, \(J_V\)-complex splitting \(T(V - B) = P \oplus P^\perp \oplus H\), where \(P\) and \(P^\perp\) are tangent and normal, respectively, to the complex lines through \(B\) in the bundle structure \(\pi\). The radial map \(\varphi_0\) preserves the splitting but scales each summand by a different positive function. (Although the fibers of \(P\) are scaled differently along their two axes, \(\varphi_0^*\) only rescales \(\omega_V|P\) since it is an area form.) Now \(J_V\) is \(\omega\)-tame on \(C\) since it is \(\omega_V\)-tame on each summand.

To verify that \(\omega|_{F_{y_0}}\) is pairwise isotopic to \(\eta_0|_{F_{y_0}}\), recall that \(\eta|_{F_{y_0}} = \eta_0|_{F_{y_0}}\), so \(\omega|_{F_{y_0}} = \frac{t}{1 + t^2}\eta_0|_{F_{y_0}}\) outside \(C\). When \(t \to \infty\) we have \(R \to r\) and \(\varphi_0 \to \text{id}_V\), so \(\omega \to \eta\). Note that \(\eta\) and \(\omega\) (for all \(t > 0\)) are symplectic on \(F_{y_0}\), although not necessarily on \(X\) (unless \(t\) is small). The required isotopy now follows from Moser’s method [9] applied pairwise to \((F_{y_0}, B)\): Starting from \(\omega\) as constructed above with \(t\) sufficiently small, let \(\tilde{\omega}_s\), \(s = \frac{1}{t} \in [0, a]\), be the corresponding family of cohomologous symplectic forms on \(F_{y_0}\) obtained by letting \(t \to \infty\) (so \(\tilde{\omega}_s = \omega|_{F_{y_0}}\) and \(\tilde{\omega}_0 = \eta_0|_{F_{y_0}}\)). Moser gives a family \(\alpha_s\) of 1–forms on \(F_{y_0}\)

with $d\alpha_s = \frac{d}{ds}\tilde{\omega}_s$, then flows by the vector field $Y_s$ for which $\tilde{\omega}_s(Y_s, \cdot) = -\alpha_s$ to obtain an isotopy with $\psi^{s}_{s} \eta_{y_0} = \tilde{\omega}_s$. If we first subtract $dg_s$ from $\alpha_s$, where $g_s: F_{y_0} \to \mathbb{R}$ is obtained by pushing $\alpha_s: TF_{y_0} \to \mathbb{R}$ from $TB^{1, \omega}_s$ down to a tubular neighborhood of $B$ and tapering to 0 away from $B$, then we can assume $\alpha_s|TB^{1, \omega}_s = 0$. Thus $Y_s$ is $\tilde{\omega}_s$–orthogonal to $TB^{1, \omega}_s$, so $Y_s$ is tangent to $B$, and its flow $\psi_s$ preserves $B$ as required, completing verification of the conditions of Addendum 2.4. (The isotopy restricts to symplectomorphisms on $B$ since each $\tilde{\omega}_s|B = \omega_B$.) Addendum 2.6 now follows immediately from the observation that the forms $\tilde{\omega}_s = \psi^{s}_{s} \eta_{y_0}$ on $F_{y_0}$ all tame $J = J'$ in this case. (For the characterization of $\Omega$, note that any two cohomologous forms taming a fixed $J$ are isotopic by convexity of the taming condition and Moser’s Theorem.)

To complete the proof of Theorem 2.3 and Addendum 2.4, we show that for sufficiently small $\delta$, any two forms $\omega_u$, $u = 0, 1$, taming structures $J_u \in J_{\delta}$ and representing $c_f \in H^2_{dR}(X)$, are isotopic, implying that $\Omega$ is canonically defined. (Note that for $0 < \delta < \varepsilon$ we have $J \in J_{\delta} \subset J_{\varepsilon}$, so $\Omega$ is then independent of sufficiently small $\varepsilon > 0$ and agrees with its usage in Addendum 2.6. Metric independence follows, since for metrics $g, g'$ on $X$ and $\varepsilon > 0$ there is a $\delta > 0$ with $J_{\delta}(g') \subset J_{\varepsilon}(g)$.) Let $J_u = j((1-u)J_0 + uJ_1)$, $0 \leq u \leq 1$. For $\delta$ sufficiently small, this is a well-defined path from $J_0$ to $J_1$, and each $J_u$ satisfies the defining conditions for $J_{\delta}$ except possibly for $\delta$–closeness to $J$. For $\delta$ sufficiently small, there is a compact subset $K$ of the bundle $\text{Aut}(TX) \to X$ lying in the domain of $j$, containing a $\delta$–neighborhood of the image of the section $J$. By uniform continuity of $j|K$, we can choose $\delta \in (0, \varepsilon)$ such that $J_u$ must be a path in $J_{\varepsilon}$, with $\varepsilon$ small enough to satisfy all of the previous requirements. Now for fixed $J_0, J_1 \in J_{\delta}$, we can assume the forms $\eta_y$ were constructed as above to agree with $\omega_V$ on $W$ and tame each $J_u | \ker df_x$, $0 \leq u \leq 1$. Perturb the entire family as before to $J'_u \in J_{\varepsilon}$, $0 \leq u \leq 1$, with each $J'_u$ agreeing with $J_V$ on a fixed $W$. For a small enough perturbation, $J'_u$ will be $\omega_u$–tame, $u = 0, 1$.

For $0 < u < 1$, the previous argument produces symplectic forms $\omega_u$ taming $J'_u$. The family $\omega_u$, $0 \leq u \leq 1$, need not be continuous. However, each $\omega_u$ tames $J'_u$ for $v$ in a neighborhood of $u$, so splicing by a partition of unity on the interval $I$ produces (by convexity of taming) a smooth family $\omega'_u$ taming $J'_u$, $0 \leq u \leq 1$, with $\omega'_u = \omega_u$ for $u = 0, 1$. Applying Moser’s Theorem to this family of cohomologous symplectic forms gives the required isotopy. \[\square\]
3 Lefschetz pencils

We now return to the investigation of Lefschetz pencils (Definition 1.4) and complete the discussion of their classification theory (Proposition 3.1, cf Principle 1.5). We then apply the results of the previous section on linear 1-systems, to show that a similar topological classification theory applies in the symplectic setting (Theorem 3.3, cf Principle 1.6).

To analyze the topology of a Lefschetz critical point (eg [8]), recall the local model $f : \mathbb{C}^n \to \mathbb{C}$, $f(z) = \sum_{i=1}^n z_i^2$, given in Definition 1.4(2). To see that a regular neighborhood of the singular fiber is obtained from that of a regular fiber by adding an $n$–handle, note that the core of the $n$–handle appears in the local model as the "disk $D$" in $\mathbb{R}^n \subset \mathbb{C}^n$. Thus, the handle is attached to the fiber $F_{1,2}$ along an embedding $S^{n-1} \hookrightarrow F_{1,2} - B$ whose normal bundle $\nu S^{n-1} = -iTS^{n-1}$ in the complex bundle $TF$ is identified with $T \mathbb{S}^{n-1}$ (by contraction with $\omega_{\mathbb{C}^n}$). We will call such an embedding, together with its isomorphism $\nu S^{n-1} \cong T^* S^{n-1}$, a vanishing cycle. Regular fibers intersect the local model in manifolds diffeomorphic to $T \mathbb{S}^{n-1}$, and the singular fiber is obtained by collapsing the 0–section (vanishing cycle) to a point. (The latter assertion can be seen explicitly by writing the real and imaginary parts of the equation $\sum z_i^2 = 0$ as $\|x\| = \|y\|$, $x \cdot y = 0$.) The monodromy around the singular fiber is obtained from the geodesic flow on $T^* S^{n-1} \cong TS^{n-1}$, renormalized to be $2\pi$–periodic near the 0–section (on which the flow is undefined), and tapered to have compact support [2, 11]. At time $\pi$, the resulting diffeomorphism extends over the 0–section as the antipodal map, defining the monodromy, which is called a (positive) Dehn twist. (To verify this description, note that multiplication by $e^{i\theta}$ acts as the $2\pi$–periodic geodesic flow on the singular fiber, and makes $f$ equivariant with respect to $e^{i\theta}$ on the base. Thus the sphere $\partial D_\epsilon$ is transported around the singular fiber by $e^{i\theta}$, returning to its original position when $\theta = \pi$, with antipodal monodromy. Away from $\partial D_\epsilon$, the monodromy is obtained via projection to the singular fiber, where it can be tapered from the geodesic flow near 0 to the identity outside a compact set by an isotopy.) Given arcs $A = \bigcup A_j$ in $\mathbb{C}P^1$ as in the introduction, connecting each critical value of a Lefschetz pencil to a fixed regular value, say $[1:0]$, we may interpret all vanishing cycles and monodromies as occurring on the single fiber $F_{[1:0]}$. The disk $D_\epsilon$ at each critical point extends to a disk $D_j$ with $f(D_j) = A_j$ and $\partial D_j$ the vanishing cycle in $F_{[1:0]}$. Following Lefschetz, we will call such a disk a thimble, but we also require that each $f|D_j : D_j \to A_j$ has a nondegenerate, unique critical point, and that there is a local trivialization of $f$ near $F_{[1:0]}$ in which each $D_j$ is horizontal.
All of the above structure on the local model of a critical point is compatible with suitable symplectic forms. (See [11].) For the standard Kähler form on \( \mathbb{C}^n \), the sphere \( \partial D \) in \( \mathbb{C}^n \) is Lagrangian in the symplectic submanifold \( F_{\varepsilon^2} \), so by Weinstein’s theorem [13] it has a neighborhood symplectomorphic to a neighborhood of the 0–section in \( T^*S^{n-1} \). This allows Dehn twists to be defined symplectically by a Hamiltonian flow in \( T^*S^{n-1}-(0\text{-section}) \) [2, 11], determining the monodromy around the singular fiber up to symplectic (Hamiltonian) isotopy. The Lagrangian embedding \( S^{n-1} \hookrightarrow F_{\varepsilon^2} - B \) determines a vanishing cycle, and will be called the Lagrangian vanishing cycle for the critical point. If \( \omega \) is an arbitrary Kähler form near 0 on \( \mathbb{C}^n \), then \( \pi_0(D) \) from \( 0 \in \mathbb{C} \) (such as \( [0, \varepsilon^2] \) above) still determines a smooth Lagrangian thimble and vanishing cycle, by a trick of Donaldson [11, Lemma 1.13]. The disk consists of the trajectories under symplectic parallel transport (ie the flow over \( A_j \) normal to the fibers) that limit to the critical point. If \( \omega \) is only given to be compatible with \( i \) at 0, this structure still exists. (In fact, \( \omega \) agrees at 0 with some Kähler form; after rescaling the coordinates, we may assume the two forms are arbitrarily close, as are the resulting disks and vanishing cycles. The case of an arbitrary taming \( \omega \) is less clear.) For a given Lefschetz pencil \( f: X - B \rightarrow \mathbb{CP}^1 \), arcs \( A \subset \mathbb{CP}^1 \), and symplectic form \( \omega \) on \( X \) that is symplectic on each \( F_y - K \) (where \( K \subset X - B \) is the critical set as in Definition 1.4(3)), any such disk at \( x \in K \) is uniquely determined and uniquely extends to a Lagrangian thimble, by symplectic parallel transport.

For a closed, oriented manifold pair \( B \subset F \) of dimensions \( 2n-4 \) and \( 2n-2 \), respectively, let \( D = D(F,B) \) denote the group of orientation-preserving self-diffeomorphisms of \( F \) fixing (pointwise) \( B \) and \( TF|B \). If \( \omega_F \) is a symplectic form on \( F \) whose restriction to \( B \) is symplectic, let \( D_{\omega_F} = D_{\omega_F}(F,B) \subset D \) be the subgroup of symplectomorphisms of \( F \) fixing \( B \) and \( TF|B \). Let \( \delta \in \pi_0(D) \) be the element obtained by a \( 2\pi \) counterclockwise rotation of the normal fibers of \( B \), extended in the obvious way (by tapering to \( \text{id}_F \)) to a diffeomorphism of \( F \). In the symplectic case, \( \delta \) canonically pulls back to \( \delta_{\omega_F} \in \pi_0(D_{\omega_F}) \), determined by the Hamiltonian flow of a suitable radial function on a tubular neighborhood of \( B \). Any vanishing cycle in \( F - B \) determines a Dehn twist in \( \pi_0(D) \) as described above. In the symplectic case, a Lagrangian embedding \( S^{n-1} \hookrightarrow F - B \) determines a symplectic Dehn twist in \( \pi_0(D_{\omega_F}) \), whose image in \( \pi_0(D) \) is generated by the corresponding vanishing cycle. If \( \omega' \) is obtained from \( \omega_F \) by a pairwise diffeomorphism of \( (F,B) \), there is an induced isomorphism \( D_{\omega_F'} \cong D_{\omega_F} \) sending \( \delta_{\omega'} \) to \( \delta_{\omega_F} \) and inducing an obvious correspondence of symplectic Dehn twists.

**Proposition 3.1** Let \( w = (t_1, \ldots, t_m) \) be a word in positive Dehn twists.
$t_j \in \pi_0(D)$, whose product $\prod_{j=1}^m t_j$ equals $\delta$. Then there is a manifold $X$ with a Lefschetz pencil $f$ whose fiber over $[1:0] \in \mathbb{C}P^1$ is $F \subset X$, whose base locus is $B$, and whose monodromy around the singular fibers (with respect to fixed arcs $A \subset \mathbb{C}P^1$) is given by $w$. For a fixed choice of $A$ and vanishing cycles determining the Dehn twists, such Lefschetz pencils are classified by $\pi_1(D)$.

**Proof** Choose $0 < \theta_1 < \cdots < \theta_m < 2\pi$. For each $j$, attach an $n$–handle to $D^2 \times F$ using the given vanishing cycle for $t_j$ in $\{e^{i\theta_j}\} \times F$. We obtain a singular fibration over $D^2$, with $m$ singularities as described above, and monodromy given by $w$. Since $\prod_{j=1}^m t_j = \delta$ is isotopic to $\text{id}_F$ fixing $B$ (but rotating its normal bundle clockwise), the fibration over $\partial D^2$ can be identified with $\partial D^2 \times (F, B)$, and the freedom to choose this identification (without losing control of $TF|B$) is given by $\pi_1(D)$. For any such identification, we can glue on a copy of $D^2 \times F$ to obtain a Lefschetz fibration $\tilde{f} : \tilde{X} \to \mathbb{C}P^1$. This $\tilde{X}$ contains a canonical copy of $\mathbb{C}P^1 \times B$, on which $\tilde{f}$ restricts to the obvious projection. The twist defining $\delta$ forces the normal bundle of $\mathbb{C}P^1 \times B$ to restrict to the tautological bundle on each $\mathbb{C}P^1 \times \{b\}$, so we can blow down the submanifold to obtain the required Lefschetz pencil.

To completely determine the above correspondence between Lefschetz pencils and $\pi_1(D)$, we must make a choice determining which pencil corresponds to $0 \in \pi_1(D)$. For a fixed Lefschetz pencil, arcs $A$ and vanishing cycles, assume the disk $D \subset \mathbb{C}P^1$ containing $A$ is embedded so that $1 \in \partial D$ maps to the central vertex $[1:0]$ of $A$. The monodromy around $\partial D$ is given to us as a product of Dehn twists, each of which is well-defined up to isotopies supported near its vanishing cycle. We choose an arc $\gamma$ in $\mathcal{D}$ from this product to the rotation determining $\delta$. (We are given that such arcs exist.) Since the rotation untwists to $\text{id}_F$ by a canonical isotopy of $F$ fixing $B$, we have now fixed an identification of the fibration over $\partial D$ with $\partial D \times (F, B)$, determining the correspondence with $\pi_1(D)$. Note that the freedom to change $\gamma$ is essentially $\pi_1(D)$, so unless we fix $\gamma$, the correspondence is only determined up to translations in $\pi_1(D)$. In the symplectic setting, we choose $\gamma$ in $\mathcal{D}_{\omega_F}$ similarly, to fix a correspondence with $\pi_1(D_{\omega_F})$. In this case, passing back to the smooth setting results in a correspondence between pencils and $\pi_1(D)$ that changes with our choice of $\gamma$ in $\mathcal{D}_{\omega_F}$ only through translation by elements of $\text{Im} \ i_*$, where $i_* : \pi_1(D_{\omega_F}) \to \pi_1(D)$ is induced by inclusion. In particular, $\omega_F$ picks out a subcollection of pencils corresponding to $\text{Im} \ i_*$ that is independent of our choice of $\gamma$ in $\mathcal{D}_{\omega_F}$. We will see that these are precisely the pencils admitting symplectic structures suitably compatible with $\omega_F$. For our symplectic classification, we wish to allow some...
flexibility in the form over the model fiber $F = F_{[1,0]}$, so we only require it to be suitably isotopic to $\omega_F$. However, the subtlety in specifying the correspondence with $\pi_1(D_{\omega_F})$ forces us to keep track of a preassigned isotopy on $F$. Thus, we classify pairs consisting of a suitable symplectic form $\omega$ on $X$ and a suitable isotopy from $\omega|F_{[1,0]}$ to $\omega_F$, up to deformations of such pairs.

To state the theorem we need one further fact. It is natural to study symplectic forms on $X$ that are symplectic on the fibers of $f$, but this condition makes no sense on the critical set $K$. For that we show that $f$ determines a complex structure $J^*$ on $TX|K$, and require our forms to be compatible with $J^*$. We also require similar compatibility normal to $B$.

**Lemma 3.2** A Lefschetz pencil canonically determines a complex structure $J^*$ on $TX|K$ (for $n \neq 1$) and on any subbundle $\nu$ of $TX|B$ complementary to $TB$. $J^*$ is obtained by restricting any local $(\omega_{\text{std}}, f)$–tame almost-complex structure $J$ defined near a point of $K$ or $B$, provided $\nu$ is $J$–complex in the latter case.

**Proof** First check that in a standard chart at $x \in K$, each hyperplane through 0 is a limit of tangent spaces to regular fibers, so it is $J$–complex for any $(\omega_{\text{std}}, f)$–tame local $J$. Any 1–dimensional complex subspace at $x$ is an intersection of such hyperplanes, so it is also $J$–complex for any such $J$. But $J_x$ is uniquely determined by its complex lines for $n \neq 1$ ([5, Lemma 4.4(a)], cf also Lemma 2.2). For $x \in B$, we obtain a suitable $J$ from the complex bundle structure $\pi$ of Definition 1.4(1), by perturbing the latter to have fibers tangent to $\nu$ as preceding Lemma 2.1. That lemma (which only requires $J$ locally) then gives uniqueness on $\nu$.

**Theorem 3.3** Let $\omega_F$ be a symplectic form on $(F, B)$ as preceding Proposition 3.1, with $[\omega_F] \in H^2 \mathbb{R}(F)$ Poincaré dual to $B$. Let $S_1, \ldots, S_m$ be Lagrangian embeddings $S^{n-1} \hookrightarrow F - B$ determining a word $w = (t_1, \ldots, t_m)$ in positive symplectic Dehn twists with $\prod_{j=1}^{m} t_j = \delta_{\omega_F} \in \pi_0(D_{\omega_F})$. If $n = 2$, assume each component of each $F - S_j$ intersects $B$. Then the corresponding symplectic Lefschetz pencils are classified by $\pi_1(D_{\omega_F})$. More precisely, a Lefschetz pencil $f: X - B \rightarrow \mathbb{C}P^1$ obtained from $S_1, \ldots, S_m$ as in Proposition 3.1, with a fixed choice of thimbles $D_j$ bounded by $S_j$ and covering the given arcs $A$, corresponds to an element of $\text{Im}(i_*)$ if and only if $X$ admits a symplectic structure $\omega$ that

1. on $(F_{[1,0]}, B)$ comes with a pairwise isotopy to $\omega_F$, defining a deformation of forms that is fixed on $B$ and $S_1, \ldots, S_m$.
is symplectic on each \( F_y - K \) and (for \( n \neq 2 \)) Lagrangian on each \( D_j \),

is compatible with \( J^* \) on \( TX|K \) (for \( n \geq 2 \)) and on the \( \omega \)-normal bundle \( \nu \) of \( B \), and

satisfies \( [\omega] = c_f \in H^2_{\text{dr}}(X) \).

For fixed \( f \) and \( D_1, \ldots, D_m \), such forms are classified up to deformation through such forms by \( \pi_2(D/D_{\omega_F}) \), and classified by \( \ker i_* \) if symplectomorphisms preserving \( f \) and fixing \( f^{-1}(A) \) are also allowed.

Note that in this classification, a single \( \omega \) with different isotopies as in (1) could represent distinct equivalence classes. Since a deformation with \( [\omega] \) fixed determines an isotopy, the isotopy classes of forms on \( X \) as above (for fixed \( f \)) are classified by the quotient of \( \pi_2(D/D_{\omega_F}) \) by some equivalence relation. In our case, \( [\omega] = c_f \) is Poincaré dual to the fiber class \( [F_{1:0}] \), the same condition that arises in Donaldson’s construction of Lefschetz pencils on symplectic manifolds [4].

**Proof** First we assume \( n \geq 3 \) and prepare to apply Theorem 2.3 by constructing a smooth family \( \sigma \) of symplectic structures on the fibers of a fixed \( f \). As in that proof, the cohomology class of \( \omega_B = \omega_F|B \) equals the normal Chern class of \( B \) in \( F \), so we can define the model symplectic form \( \omega_V \) and almost-complex structure \( J_V \) on \( V \subset X \) as before (starting from any fixed choice of \( \pi : V \to B \) as in Definition 1.4(1) and any \( \omega_B \)-tame \( J_B \) on \( B \)). By Weinstein’s theorem, we can assume \( \omega_V \) agrees with \( \omega_F \) near \( B \) on \( F = F_{1:0} \). At each critical point \( x_j \), choose a standard chart for \( f \) (necessarily inducing \( J^* \) on \( T_{x_j}X \)). Then \( D_j \) is not tangent to any complex curve at \( x_j \) (since \( f|D_j \) is nondegenerate and \( f \) is constant or locally surjective on any complex curve). There is a complex isomorphism \( (T_{x_j}X, T_{x_j}D_j) \cong (\mathbb{C}^n, \mathbb{R}^n) \), and \( \omega_{\mathbb{C}^n} \) pushes down to a symplectic form \( \omega_j \) near \( x_j \), compatible with \( J^* \) at \( x_j \), and Lagrangian on a disk \( \Delta_j \subset D_j \) containing \( x_j \). Since \( D_j \) is a thimble for \( f \), we can identify the fibers over \( \text{int} A_j \) with \( F \) by an isotopy in \( X \) fixing \( B \) and preserving \( D_j \), so that \( S_j \) matches with \( \partial \Delta_j \) (with the correct normal correspondence) and their tubular neighborhoods in the fiber correspond symplectically (by Weinstein) relative to \( \omega_F \) and \( \omega_j \), respectively. We can assume (by \( U(2) \)-invariance of \( \omega_V \)) that the isotopy is \( \omega_V \)-symplectic near \( B \), and that it agrees near \( K \) with symplectic parallel transport in the local model. Thus it maps the tubular neighborhood of \( \partial \Delta_j \) in its fiber to a neighborhood of the singularity in the singular fiber, by a map that is a symplectomorphism except on \( \partial \Delta_j \), which collapses to the singular point (cf [11]). Pulling \( \omega_F \) back by the isotopy now gives a family \( \sigma \) of symplectic structures on the fibers over \( A \), agreeing with...
the local models $\omega_V$ and $\omega_j$ near $B$ and $K$. Extend $\sigma$ over a disk $D \subset \mathbb{C}P^1$ whose interior contains $A - \{1:0\}$. Since $\prod_{j=1}^m t_j = \delta_{\omega_F}$ is symplectically isotopic to $\text{id}_F$ fixing $B$ (rotating its normal bundle), we can fix a path $\gamma$ in $D_{\omega_F}$ as above and identify all fibers over $\partial D$ with $(F, B)$ so that $\sigma$ is constant. The set of all such choices of identification (agreeing with the given one on $F_{\{1:0\}}$ and $TF|B$, up to fiberwise symplectic isotopy fixing $TF|B$) is then given by $\pi_1(D_{\omega_F})$. Passing to $\pi_1(D)$ classifies Lefschetz pencils $f$ as in Proposition 3.1, and $\sigma$ has a constant extension over the remaining fibers of any $f$ coming from $\text{Im} i_s \subset \pi_1(D)$ (for any choice of element in the corresponding coset of $\text{ker} i_s$).

Next we apply Theorem 2.3. By contractibility of the space of $\sigma$–tame complex structures on each $T_x F_{f(x)}$, we obtain a $\sigma$–tame family of almost-complex structures on the fibers. After declaring a suitable horizontal distribution to be complex, we obtain a fiberwise $\sigma$–tame complex structure $J$ on $X$, which we may assume agrees with $J_V$ near $B$ and with the structures on the chosen standard charts near the critical points. Now $(f, J)$ is a linear 1–system as required. Set $\nu = (\ker d\pi)|B$. For each $F_y$, define $\eta_y$ on a neighborhood $W_y$ by pulling back $\sigma|F_y$ by a map $r: W_y \to W'_y$ collapsing $W'_y$ onto $F_y$ away from $B \cup K$ (cf proof of Theorem 2.3). Then each $\eta_y$ agrees with $\omega_V$ on a fixed neighborhood of $B$, and with $\omega_j$ on a neighborhood of the critical point if $F_y$ is singular. We can assume each $\eta_y|D_j \cap W_y = 0$. Let $\zeta$ be any form on $X$ representing $c_f$, agreeing with $[\eta_{\{1:0\}}]$ near $F_{\{1:0\}}$, and vanishing on each thimble. (Note $c_f|F_{\{1:0\}} = [\omega_F] = [\eta_{\{1:0\}}]|F_{\{1:0\}}$ as required, and the thimbles add no 2–homology to $W_{\{1:0\}}$ since $n \geq 3$.) The condition $[\eta_y - \zeta] = 0 \in H^2_{\text{dR}}(W_y, B)$ is trivially true for $y = [1:0]$. The case of any regular value $y$ then follows since $F_y$ comes with an isotopy rel $B$ in $X$ to $F_{\{1:0\}}$, sending $\eta_y|F_y$ to $\omega_F$. For a critical value, we can assume $W_y$ is obtained from a tubular neighborhood of a regular fiber by adding an $n$–handle. Since $n \geq 3$, the handle adds no 2–homology, so the condition holds for all $y$. Now Theorem 2.3 and Addendum 2.6 provide a unique isotopy class of symplectic forms $\omega$ on $X$ taming $J$, with $[\omega] = c_f$ and $\omega|F_{\{1:0\}}$ pairwise isotopic to $\omega_F$. This $\omega$ can be assumed to satisfy the required conditions for Theorem 3.3: Compatibility of $\omega$ with $J^* = J$ is given on $\nu$. It follows on $K$ since $\omega$ is made from $\omega_t = t\eta + f^*\omega_{\text{std}}$; the second term vanishes on $K$, and the first agrees with each $t\omega_j$ if we set $\{\tilde{y}_1, \ldots, \tilde{y}_m\} = f(K) \cup \{[1:0]\}$ when applying Theorem 2.5. Similarly, the thimbles $D_j$ are Lagrangian, since $f^*\omega_{\text{std}}$ vanishes on them, as does $\eta$ if the forms $\alpha_y$ arising from Theorem 2.5 are chosen to vanish there. (This can be arranged since $H^1_{\text{dR}}(S^{n-1}) = 0$ for $n \geq 3$, and $\alpha_{[1:0]} = 0$.) The forms $\bar{\omega}_s = \psi^*_s \eta_{\bar{y}_0}$ in the deformation constructed for (1) also restrict to scalar multiples of $\eta = 0$ on each $S_j$ as required.

For fixed $X$ and $f$, we wish to compare two arbitrary symplectic structures
\( \omega_u, u = 0, 1, \) satisfying the conclusions of the theorem. We adapt the previous procedure to 1-parameter families, beginning with the construction of \( \sigma \). For \( u = 0, 1 \), choose \( \pi_u: V_u \to B \) with fibers tangent to the \( \omega_u \)-normal bundle \( \nu_u \to B \), and construct structures \( \omega_{V_u} \) and \( J_{V_u} \) as before, using the Hermitian form \( \omega_u|\nu_u \). By Weinstein (cf proof of Theorem 2.3), we can assume \( \omega_u = \omega_{V_u} \) near \( B \) after an arbitrarily \( C^1 \)-small isotopy. (First isotope \( \pi_u \) to get equality on \( F_{[1:0]} \), preserving the fibers of \( f \), then isotope \( \omega \) fixing \( F_{[1:0]} \).) Let \( \sigma_u \) be the family obtained by restricting \( \omega_u \) to the fibers. Symplectic parallel transport gives a fiber-preserving map \( \varphi_u: A \times F_{[1:0]} \to X \) for which \( \varphi_u^* \sigma_u \) is constant, and the Lagrangian thimbles \( D_j \) are horizontal. Now smoothly extend \( \pi_u, \omega_{V,u}, J_{V_u} \) and \( \varphi_u \) for \( 0 \leq u \leq 1 \). Also extend \( \omega_u \) near \( K \) by linear interpolation, so that it is \( J^*- \)compatible on \( K \) and has Lagrangian disks \( \Delta_j, 0 \leq u \leq 1 \). Condition (1) gives a pairwise isotopy from \( \omega_0 \) through \( \omega_F \) to \( \omega_1 \) on \( (F_{[1:0]}, B) \). Use this to extend \( \sigma_u \) for \( 0 \leq u \leq 1 \) to \( F_{[1:0]} \) with \( \sigma_{1/2} = \omega_F \), and then extend as before to the fibers over \( A \) and \( D \), agreeing with \( \omega_{V,u} \) near \( B \) and \( \omega_u \) near \( K \), and with \( \varphi_u^* \sigma_u \) constant for each \( u \).

To complete the construction of \( \sigma_u, u \in I = [0, 1] \), over the fibers of \( id_I \times f \) on \( I \times X \), we attempt to fill the hole over \( (0,1) \times (\mathbb{CP}^1 - D) \), encountering obstructions. As before, we can smoothly identify all fibers over \( I \times \partial D \) with \( F_{[1:0]} \) so that the family \( \sigma_u \) is constant for each \( u \). To fix this identification \( \tau_u \) for each \( u \), pull the preassigned path \( \gamma \) back from \( D_{\omega_F} \) to \( D_{\sigma_u[F_{1:0}]} \) by the given isotopy. This moves the spheres \( S_j \), but the same isotopy shows how to restore them to their original position through families of Lagrangian spheres (by the last part of (1)), yielding a canonically induced path \( \gamma_u \) from the required representative of \( \prod t_j \delta \sigma_u \) in \( D_{\sigma_u[F_{1:0}]} \), which determines \( \tau_u \). Now let \( \widetilde{\tau}_0 \) be the identification of all fibers over \( \{0\} \times (\mathbb{CP}^1 - \text{int} D) \) with \( F_{[1:0]} \) by \( \omega_0 \)-symplectic parallel transport along straight lines to \( [1:0] \) in \( \mathbb{CP}^1 - \text{int} D \). Comparing \( \widetilde{\tau}_0 |\partial D \) with \( \tau_0 |\partial D \), we obtain the element of \( \pi_1(D) \) classifying \( f \), and see that this must lie in \( \text{Im} i_* \) (being explicitly represented by a loop in \( D_{\sigma_0[F_{1:0}]} \simeq D_{\omega_F} \)). The corresponding construction of \( \widetilde{\tau}_1 \) from \( \omega_1 \) also gives \( f \), so \( \widetilde{\tau}_0 |\partial D \) and \( \widetilde{\tau}_1 |\partial D \) differ by an element \( \beta \) of \( \text{ker} i_* \) (after we extend each \( \widetilde{\tau}_u \) over \( I \times \partial D \) to \( u = 1/2 \) so that we can work with the fixed symplectic form \( \omega_F \)). Similarly, a direct comparison of \( \widetilde{\tau}_0 \) and \( \widetilde{\tau}_1 \) yields an element \( \alpha \in \pi_2(D, D_{\omega_F}) \cong \pi_2(D/D_{\omega_F}) \) with \( \partial_\alpha = \beta \). If \( \alpha = 0 \), we can extend \( \sigma_u \) over \( X \) for \( 0 \leq u \leq 1 \). If only \( \beta = 0 \), then we can perturb \( \widetilde{\tau}_1 \) so that \( \alpha \in \pi_2(D) \), and \( \alpha \) provides a self-diffeomorphism of \( X \) preserving \( f \) and fixing \( f^{-1}(D) \), after which \( \sigma_u \) extends. These vanishing conditions are also necessary for the deformation and symplectomorphism, respectively, specified by the theorem, since any allowable deformation \( \omega_u, 0 \leq u \leq 1 \), determines a family \( \widetilde{\tau}_u \) as above interpolating.
between \( \tilde{\tau}_0 \) and \( \tilde{\tau}_1 \), showing that \( \alpha = 0 \). (Note that the family \( \omega_u \) comes with a smooth family of isotopies from \( \omega_u|F_{[1:0]} \) to \( \omega_F \) as in (1), allowing us to continuously pull back \( \gamma \) to each \( D_{\sigma_u}|F_{[1:0]} \) as before, to define the required interpolation \( \tau_u \) between \( \tau_0 \) and \( \tau_1 \) in the absence of the condition \( \sigma_{1/2}|F_{[1:0]} = \omega_F \).)

To complete the proof for \( n \geq 3 \), it suffices to construct the required deformation between \( \omega_0 \) and \( \omega_1 \) from the completed family \( \sigma_u \) on \( I \times X \). First find a continuous family \( J_u \) of fiberwise \( \sigma_u \)-tame almost-complex structures on \( X \) as before, using a horizontal distribution that is \( \omega_u \)-orthogonal to the fibers when \( u = 0,1 \). Then \( J_u \) is \( \omega_u \)-tame, \( u = 0,1 \). For \( 0 < u < 1 \), the previous argument now produces suitable symplectic structures \( \omega_u \) on \( X \), with \( \sigma_u \) replacing \( \omega_F \) in (1). The family \( \omega_u \), \( 0 \leq u \leq 1 \), need not be continuous (particularly at 0,1), but we can smooth it as for Theorem 2.3, with a partition of unity on \( I \), obtaining the required deformation \( \omega'_u \): First pull each \( \omega_u \) back to a neighborhood \( I_u \) of \( u \in I \), by a map preserving the bundles \( \nu_u \), forms \( \omega_B \) and disks \( D_j \). For \( I_u \) sufficiently small, the required conditions (1–4) are preserved, where the isotopy in (1) from \( \omega_u \) to \( \sigma_u \) on \( F_{[1:0]} \) at each \( v \in I_u \) is through \( J_v \)-taming forms (by Addendum 2.6) and is defined to be constant for \( u = 0,1 \). Splicing by a partition of unity on \( I \) preserves (2–4), producing the required family \( \omega'_u \) and a 2-parameter family of symplectic structures on \( F_{[1:0]} \), interpolating between \( \omega'_u \) and a convex combination \( \sigma'_u \) of nearby forms \( \sigma_v \) for each \( u \). If the intervals \( I_u \) were sufficiently small, we can extend by \((1 - s)\sigma'_u + s\sigma_u\) to obtain a 2-parameter family of symplectic structures from \( \omega'_u \) to \( \sigma_u \), all agreeing with \( \omega_F \) on \( B \) and each \( S_j \), and constant for \( u = 0,1 \). Moser’s technique, parametrized by \( u \), now produces a 2-parameter family of diffeomorphisms of \((F,B)\), which can be reinterpreted as a smooth family of isotopies as in (1) from \( \omega'_u|F_{[1:0]} \) to \( \omega_F = \sigma_{1/2}|F_{[1:0]} \), interpolating between the given ones for \( \omega_0, \omega_1 \).

For the remaining case \( n \leq 2 \), inclusion \( D_{\omega_F} \subset D \) is a homotopy equivalence, so we must show each \( f \) has a unique deformation class of structures \( \omega \) as specified. The case \( n = 1 \) \((f \colon X \to \mathbb{CP}^1 \) a simple branched covering\) is trivial, so we assume \( n = 2 \). Then \( f \) is a hyperpencil, so \([5, \text{Theorem 2.11(b)}]\) gives the required form \( \omega \), provided we arrange \( J^*\)-compatibility as before. Uniqueness of the deformation class follows the method of proof of \([6, \text{Theorem 1.4}]\) with \( m = 0 \) and \( K \) replaced by \( K \cup B \): Given two forms \( \omega_u \), \( u = 0,1 \), as specified in Theorem 3.3, we can find an \((\omega_{std}, f)\)-tame, \( \omega_u \)-tame almost-complex structure \( J_u \) for each \( u \) \((\text{cf also } [5, \text{Lemma 2.10}])\). We interpolate to a family \( J_u \), \( 0 \leq u \leq 1 \) \((\text{eg by contractibility in } [5, \text{Theorem 2.11(a)}])\), and construct the required deformation \( \omega_u \), \( 0 \leq u \leq 1 \), using a partition of unity.
on $I$ as before. Conditions (1–4) for each $\omega_u$ are easily verified, with only (1) requiring comment: We are given isotopies rel $B$ from $\omega_u|F_{[1:0]}$ to $\omega_F$, $u = 0, 1$. Moser provides an isotopy rel $B$ from $\omega_0$ to $\omega_1$ on $F_{[1:0]}$. Combining these three isotopies gives a path representing an element of $\pi_1(D', D'_F)$, where the prime indicates rotations of $TF|B$ are allowed. This group vanishes, allowing us to extend our path into the required 2–parameter family of diffeomorphisms. □
